Two years ago she again came to me and I curetted her a second time, and during the operation made out a small fibroid in the anterior wall of the uterus. The scrapings from both of these operations were examined microscopically and pronounced perfectly benign. Last January she came to me a third time. Although her general health was better than it had been for several years and her extreme anemia had disappeared to a considerable extent, probably owing to persistent tonic treatment, she was still losing a large amount of blood at each period, the flow lasting between one and two weeks, forcing her to keep her bed. I put her on thyroid, beginning with 3 grains daily and increasing 1 grain daily. The drug in her case was not well borne. As soon as she went beyond 6 grains a day her ankles and legs would swell, albumin would appear in her urine, her heart action would become rapid and irregular, and her appetite would disappear. A discontinuance of the drug for a few days would bring about a return to a normal condition. While the thyroid was being used in 4- to 6-grain doses daily, the excessive bleeding was held in check and the patient's general health and strength improved. She was under observation six weeks, and since her return home has in an irregular manner continued the use of a small amount of the drug, with the result that the excessive flow has been held fairly well in check.

Case V.—Mrs. R. W., white, aged thirty-five years, widow, no children. In January, 1895, I opened her abdomen on account of enlarged tubes, the result of a prolonged inflammatory condition. I found the intestines agglutinated together and the pelvic cavity completely walled off by lymph. As she took the anesthetic very badly, I simply washed out the abdomen and closed the incision. She did perfectly well and during the following few months gained sixty pounds in weight. During the latter part of 1897, however, she complained of discomfort in the left iliac region together with rather excessive menstrual flow.

She entered my private hospital on November 9th, there being present a very excessive menstrual discharge. On November 15th examination under ether showed an elastic enlargement in the line of the left tube, and after curetting her thoroughly I drained the tube through the vagina, the fluid apparently being a bloody serum. At this operation I made out a fibroid thickening in the upper portion of the left side of the uterus. The scrapings were reported benign. The two succeeding menstrual flows were excessive in amount and I ordered thyroid to be taken as in the preceding cases. This patient could take 6 grains daily for a limited time without bad results, but even that quantity if persisted in caused loss of appetite and marked dyspeptic symptoms, together with a very rapid and irregular action of the heart, and she had to limit herself to 4 grains daily. This, however, was sufficient to keep the excessive loss of blood in check. The menstrual flow became normal in amount and character and has so remained.

From these five cases I came to the following conclusions: (1) That, whereas some patients can take comparatively large doses of thyroid with impunity, others are injuriously affected by small amounts, and that, in using it, one should begin with a minimum dose, say 3 grains daily, increasing the amount very slowly and watching its effect upon the heart and kidneys carefully; (2) that in cases of bleeding fibroids, thyroid has a very marked influence in checking the excessive loss of blood, and that in certain cases at least its use is followed by a diminution in the size of the growth; (3) that its use, in doses appropriate to the individual, is followed by improvement in the general health, this being probably due to the cessation of excessive loss of blood.

Dr. Whitney's report is as follows:

By our present methods of blood examination it is impossible to demonstrate any alteration in the blood which will explain the changes taking place in the organism under the influence of thyroid. The only change, as the analyses show, which can be demonstrated is a moderate increase in the percentage of small mononuclear cells with a corresponding decrease in the percentage of polymorphonuclear neutrophiles. There might be, it is true, an increase in the oxidation equivalent of the blood or an increase in the volume of blood, but neither can be determined by any of our methods with any degree of exactness. In the cases where an apparent anemia is cured by the action of thyroid, the action may be better explained by considering the cure as simply the result of a local action upon some physical condition underlying the anemia (Case I.). In Case II., the patient suffering from mental trouble could not be induced to eat or exercise. Under thyroid the mental and physical conditions both improved. As

a consequence the blood condition also improved. In Case III. the condition was one of intense anemia from bleeding fibroids. Under treatment with thyroid, the bleeding ceased, necessarily the condition of the blood improved, as it probably would have done under any other treatment which would have stopped the hemorrhage, making the blood secondary to the change in the fibroid. (See Case II., of Dr. Richardson's blood-count.)

Now with regard to its effects upon metabolism. All the cases which I have studied during the past two years, some superficially, others carefully, show a considerable decrease in the amount of nitrogen and salts eliminated in the urine. This fact, taken in connection with the undoubted decrease in weight in persons suffering from obesity, renders it positive that the decrease in weight must be due to the increase in the metabolism of fats in the body. Carbohydrates are stored up in the body in only moderate amounts at any time, the increase in weight being due to an increase in the amount of fats (hydrocarbons) in the body. This narrows the increase in metabolism to an increase in the metabolism of fats. Now by oxidation of fats the products formed are CO_2 and H_2O, both of them eliminated principally by the lungs, and both difficult to estimate except by very elaborate apparatus. Whatever histologic connection there may be between myofibromata of the uterus and connective-tissue cells of areolar and adipose tissue I must leave to the histologist and gynecologist to discover. I think the relation must be nearer than is commonly supposed.

The following reports of the blood examination in Cases I. and II. were furnished me by Dr. Richardson of Mount Hope, and I am sure they are correct. The results agree in the main with those I have previously obtained and with statements contained in the literature on the subject of thyroid medication:

CASE I.

Before treatment:
- Erythrocytes 4,528,000
- Leucocytes 8500

Differential count:
- Small mononuclear ..... 17.6 per cent.
- Large " ..... 8.4 "
- Eosinophiles ..... 1.8 "
- Multinuclear ..... 72.2 "

Specific Gravity 1053
Hemoglobin ..... 75 per cent.
No basophilic perinuclear granules observed with dahlia.

After one week's treatment, patient taking 5 grains three times daily:
- Erythrocytes 4,835,000
- Leucocytes 8000

Differential count:
- Small mononuclear ..... 27.9 per cent.
- Large " ..... 9.6 "
- Eosinophiles ..... 1.2 "
- Multinuclear ..... 62.3 "

Specific Gravity 1053
Hemoglobin ..... 75 per cent.
No basophilic perinuclear granules with dahlia.

CASE II.

Before treatment:
- Erythrocytes 3,648,000
- Leucocytes 9400

Differential count:
- Small mononuclear ..... 10.0 per cent.
- Large " ..... 6.8 "
- Eosinophiles ..... 1.0 "
- Polynuclear ..... 81.2 "

Specific Gravity 1045
Hemoglobin ..... 45 per cent.
Perinuclear basophilic granules ..... 0.5 "

After three-weeks' treatment, patient taking 2½ grains three times daily:
- Erythrocytes 4,320,000
- Leucocytes 8000

Differential count:
- Small mononuclear ..... 21.2 per cent.
- Large " ..... 7.4 "
- Eosinophiles ..... 2.1 "
- Polynuclear ..... 69.3 "

Specific Gravity 1054
Hemoglobin ..... 78 per cent.
Perinuclear basophilic granules ..... 0.15 "

From published reports in connection with typhoid treatment it has been found that changes occur in blood as follows: (1) a slight increase in the number of mononuclear-cells; (2) a corresponding decrease in the percentage of the polymorphonuclear neutrophiles; (3) an increase in the oxygenating power of the blood.

The urine shows, in general terms: (1) a decrease in the amount of nitrogen eliminated; (2) a decrease in all nitrogenous constituents; (3) a decrease in the amount of mineral matters; (4) albuminuria if too large doses are used.

Bodily conditions. In obesity: (1) a decrease in weight; (2) no corresponding decrease in strength; (3) taken in connection with urinary analysis it indicates that the increase in metabolism must fall on hydrocarbons and carbohydrates, the increased metabolism and change of which acts as a saving principle to the proteids of the body.

From Berlin, where Dr. Whitney at present is working with Professor Thierfelder, he writes as follows regarding thyroid:

"In accordance with my promise, I have been trying to look up the thyroid treatment and its effects more thoroughly, but so far have been unable to find any satisfactory report of its results. The effects upon metabolism may be briefly stated as follows: (1) Upon the nitrogenous metabolism and elimination its influence is stated by some to remain normal; by others, including Chittenden, the elimination is stated to be slightly but uniformly increased, the diet remaining the same. Those observers who have found the daily elimination of nitrogen the same or decreased have possibly failed to

take into account the injurious effect of large doses of thyroid upon the appetite and digestion, with consequent decrease in the amount of food (and nitrogen) ingested. The increase in the amount of nitrogen eliminated remains, however, always slight. (2) The effect upon general metabolism is shown by the decrease in weight which follows the prolonged administration of thyroid, especially if in excessive doses. As there is not a corresponding increase in the amount of nitrogen eliminated, this loss must come chiefly from the non-nitrogenous elements of the body, that is, fats or the carbohydrates. This is apparently proven in the following ways: (*a*) There is a marked increase in the amount of CO_2 eliminated by the body, showing increased oxidation of the carbonaceous materials of the body. (*b*) The loss of weight is most pronounced in those suffering from obesity, leading to its use as an 'anti-fat' remedy. (*c*) In mild cases of diabetes mellitus the sugar may be made to diminish or disappear entirely under the use of thyroid. These effects may be explained by one or both of the following hypotheses: (1) It may exert a specific stimulating effect upon the areolar tissues of which adipose tissue forms only a modification, due to the deposition of fats. (2) It may increase oxidation by increasing the oxidizing power of the blood. Its demonstrable effects upon the blood are limited, usually showing a slight increase in the number of mononuclear leucocytes, other changes in the blood, found at times, being explicable by changes in the organism, the alteration in blood constitution being secondary, as for example, the increase in hemoglobin and red corpuscles after administration of thyroid in bleeding fibroids.

"The explanation of its action upon fibroids must be hypothetical only. Analyses of dried fibroids show them to contain about fifteen per cent. of nitrogen (average) and only 1.5 per cent. of fats (matter soluble in boiling ether). Its action may be that stated above, that is, stimulation of the tissue composing the fibroid with resultant absorption, or by an increase in the oxidizing power of the blood, with absorption of the fibroid as a secondary effect."

SACROILIAC DISEASE (TUBERCULAR).

By L. L. McARTHUR, M.D.,
of Chicago.

Since the mechanism of joint and bone infections has been cleared up by the experimental work of the bacteriologist and pathologist, there remains but little divergence of opinion as to the possibility of invasion of any of the body-joints by infective elements, the frequency of invasion being almost directly proportional to the activities of, and forces acting on, the given joint. Omitting direct macroscopic infective embolism, it has become almost a surgical axiom that there must be two etiologic factors in the induction of a joint inflammation: first, the infective elements, such as pus-microbes, gonococcus, tubercle, rheumatism, staphylococcus, *et id genus omne*, and, second, trauma. By trauma we are to understand not merely direct or indirect violence alone (though this is one of the most frequent forms), but likewise cold, wet, excessive use, pressure, and even chemical irritations, which may determine the localization at any one point of the infective elements.

How? It should now be well known and remembered (1) that when bacteria in moderate number gain access to the circulation, whether artificially or by disease, they are immediately captured, enveloped, swallowed by the leucocytes, except when present in overwhelming numbers, and carried to the liver, spleen, and other emunctory organs, where they are slowly disintegrated, the products of the disintegration being stored up in such large quantities as often to multiply many times the size of these organs. (2) That this fact is true of the leucocyte; while the leucocyte remains in the blood-vessels it is not killed by such ingestion of micro-organisms. (3) That *ubi irritatio ibi fluxus* is as true of the white as well as the red blood-corpuscle. (4) Should this irritation or trauma occur to an organism, some of whose leucocytes chanced to be charged with pathogenic bacteria, the determination of leucocytes to the irritated part, some laden with bacteria, follows with certainty. (5) Let the leucocyte, so handicapped, however, wander out from the blood current, and it dies through the lack of the protective antitoxin in the flowing blood streams; immediately the contained bacteria begin to reproduce, the inflammatory war is on, more leucocytes called by their chemotactic sense of present toxins, more deaths through lack of protective serum, more exudate. This, true in the case of pus-microbes, holds similarly true with our other common pathogenic organisms.

With this understanding of the mechanism of infection of a joint, we can easily conceive how processes so common in the great joints of the body, exposed as they are to so many forms of trauma, may with diminished frequency occur in those less exposed, less mobile, less vascular articulations or semi-joints, the sacroiliacs. We are all familiar with the class-room experiment of injecting into the jugular circulation of one or two dogs staphylococcus cultures, and then fracturing the femur in each or bruising the knee. The one with the pus-microbes will, with unerring certainty, have a localized sup-

puration, the other not. Schüller has done the same with tubercle bacilli.

Since it is the specific organism which determines the infection, and the trauma the localization, it is as conceivable that we may have a tubercular, suppurative, gonorrheal, rheumatic or puerperal infection of the joints in question as well as those of other parts of the body, the relative frequency being determined by the active or passive parts played in the motions of the body. While it is true that these joints differ somewhat anatomically from the others, the better anatomists agree as to the presence of (1) a synovial membrane, (2) a capsular ligament, (3) cartilage, (4) ligaments, and (5) a smooth articular surface. We are not surprised, therefore, to find in the literature cases described as belonging to each of the quoted types of disease affecting this joint, as they do the other body articulations. I have made this digression for the purpose of showing the fallacy of the position taken by some, that on anatomical grounds those inflammations, whose localization depends upon the existence of a synovial membrane, cannot occur here: namely, gonorrheal, rheumatic, syphilitic, or puerperal; secondly, because others may never have seen any.

My aim in selecting this subject for our discussion has not been to present to you a classical *résumé*; this has already been accomplished in a masterly way by Van Hook, who reviews the entire literature to 1889 with fifty-eight well-recorded cases and adds one by himself, but to present what practical points I have gleaned from personal experience with five advanced and a sixth possibly incipient case (all tubercular), as well as to recall your attention to a disease which must be thought of in making a diagnosis in every suspected hip-joint disease, sciatica or low-lying Pott's, and which, once seen, will probably remain indelibly fixed in the memory.

When the bones constituting this joint are examined the smooth auricular surface of the ilium attracts attention, and the roughened larger area for the attachment of the strongest ligament in the body. The pelvis being held in the position it occupies when erect shows that the anterior is really, in life, the inferior surface, and the converse for the posterior. The proximity of the first, second, and third sacral nerves of the sacral canal, the internal iliac vessels, and the rectum in front once recalled will make clear many of the symptoms, render plain the sequelæ, and suggest the surgical treatment. Occurring in all periods of life, Velpeau shows that 37½ per cent. occur between 20 and 25 years, 22 per cent. below 15 years, and before 5 and after 60 very rarely.

Symptoms.—Chauvel believes cavalry officers most frequently affected. Males much oftener than females. Erichsen, from a clinical study, considers the chief symptoms as (1) pain, (2) lameness, (3) changed attitude and length, (4) tumefaction, and (5) abscess.

Pain.—Consider the joint, its functions, its relations, and it is easily understood that pain will be an early, persistent, and prominent symptom. Like any other joint, pain will be in the immediate neighborhood, in lower lumbar regions, in buttocks; and, since the sacral nerves, the obturator, genitocrural, and the anterior crural nerves pass in close relation to the joints anteriorly, any irritation to their trunks will be referred to their terminal distribution; hence, the anterior and posterior thigh areas the knee, and the external genitals are complained of. It will be increased by supporting the weight of the trunk; hence, felt either standing or sitting; made worse by jarring in that position, relieved by lying on the back, but aggravated by lying on the affected side.

The surgeon takes advantage of this knowledge as one of his chief aids to diagnosis by mechanically driving the two joints' surfaces together by counter-pressure over the ilia when the most constant symptom of pain is made manifest. Pain is sometimes wholly absent on pressure over the joint posteriorly, probably in the early cases of affections involving only the anterior portion of the joint.

The rectum lying in front of the inflamed joint will attract the patient's attention by pain, with constipated bowel movements, just prior to evacuation by pressure on the anterior joint, *i.e.*, as the fecal mass passes the bulging made by the inflammatory pelvic exudate. This was a prominent symptom in Cases II. and IV., about to be reported, and suggests the immense importance of a rectal exploration in every case of doubtful hip, iliac, or sciatic disease.

Posture.—Intuitively the patient shifts the weight of the body to the opposite side, as Sayre thinks, to make extension by the weight of the leg, takes short steps to avoid motion at this joint, sets the heel and toe down flat on the affected side, and through efforts to somewhat fix the sacroiliac joint may adduct or abduct the limb to an extent sufficient to make an *apparent* shortening or lengthening, which may misdirect one's thoughts to the hip-joint unless on guard, through the knowledge that this may be likewise induced by sacroiliac disease. By a similar effect on the pelvic veins to that occurring in milk-leg, or pelvic neoplasm, there may be marked edema of the lower extremity. The lack of use of the muscles here in the efforts of the patient to prevent pain soon induces an atrophy on that side, the gluteal region may become flattened, and limping is always pres-

ent. The persistence of the tilting of the pelvis may induce a lateral compensatory curvature above.

Tuberculosis of other joints occurs in one of two ways: by primary synovial tuberculosis, or by bone tuberculosis and extension to the joint, never beginning in the other joint structures, and this holds equally true of the joint under consideration. Therefore, when the synovial invasion occurs there is first what has been called the "moist" variety, of Velpeau, and when extension by the rarefying tuberculous osteitis to the joint, the "dry" or granulating variety. Now, as the synovial portion of the articulation lies at the anterior, or, if we consider the erect posture, the inferior quadrant, it is easily seen how the larger proportion of patients have the cold abscesses appear intrapelvicly, at the point of greatest dependence, where they may burrow in the several manners hereafter mentioned: (1) Forward into the rectum; (2) outward along the pyriformis muscle and sacral plexus behind the great trochanter; (3) downward along the rectum to the ischiorectal fossa; (4) forward and outward along the psoas muscle beneath Poupart's ligament; or (5) upward over the crest of the ilium.

In a certain proportion of cases a fluctuating tumor forms over the posterior aspect of the joint first, and may open directly backward, or burrow up along the erector spinæ muscle to the lumbar region. More frequently this tumor is secondary to the anterior abscess formation and only betokens the spreading of the disease. All but two of the patients whose cases are to be reported here came to me through the hospitals and, therefore, were not seen in the very early stage of the disease, and I cannot therefore add any testimony to the statements made by the authorities that in the very early stages of the disease there is usually to be found a thickening and tumefaction over the dorsal line of the joint, but I should think this to be necessarily true, at least in those in whom, later, the cold abscesses show posteriorly.

Methods of Opening.—When the abscess empties into the rectum (often the first objective symptom noted), the patient calls attention to the purulent discharge, and often is soon seized with the classic symptoms of sepsis—chill, fever, and sweating, as a result of the mixed infection of the tubercular abscess cavity by the intestinal bacteria, and then first calls the physician. Such a sequence followed, too, the spontaneous or surgical opening of such an abscess prior to very recent years, for in the absence of the strictest antiseptic technic a mixed infection takes place similar to that which formerly occurred in opening a psoas abscess, therefore inducing the preantiseptic surgeons to avoid opening, or when opening to resort to the valvular opening with the vain hope of preventing any air or other external vicious elements from gaining access. Ridlon, in writing on this subject, takes the unique position that in this situation the abscess is to be opened, while in the psoas it is not.

Every ischiorectal abscess, especially when of the cold or painless variety, should be carefully examined prior to its opening in order to detect its possible sacroiliac origin. If of such origin, in my opinion it would be better to first excise the joint and drain posteriorly before a mixed infection occurs, unavoidable with an opening near the anal margin.

With the abscesses opened spontaneously or surgically and fistulæ established, whether near the trochanter, under Poupart's ligament, or behind the joint, the direction taken by the probe will be *toward* the sacroiliac junction, *away* from the hip, and though it fail to touch denuded bone, will lead so near to it as to justify the suspicion of the disease at that location. In some cases of mixed infection the spinal canal has been invaded; thus Ashhurst has seen a fatal case by an extension to the sacral canal and cord, as has also Satterthwaite.

Localized elevation of temperature over the joint has been recommended by Holmes, and utilized by Sayre, as a diagnostic aid. When next an opportunity offers I shall endeavor to demonstrate the rarefying osteitis by the X-ray photograph and localize the same, thus gaining information both as to the extent and the position of the focus.

Diagnosis.—Stedman has arranged a convenient differential diagnosis table as follows:

Sacroiliac Disease.

1. Rare.
2. Hip motions free.
3. Young adult males.
4. Spine not rigid though often held stiff.
5. Limb apparently elongated and not infrequently abducted.
6. Characteristic position.
7. Cautious passive movement at hip, painless.
8. Pain usually localized.
9. When sinus, probe goes direction sacroiliac joint.

Hip-Joint Disease.

1. Common.
2. Restricted.
3. Childhood both sexes.
4. Spine freely movable.
5. Character varies.
6. No characteristic position; varies.
7. All painful.
8. In hip, knee, or thigh.
9. To joint of hip.

Pott's Disease.

1. Not common so low down.
2. Free, except when psoas is contracted.
3. Not rare in adults.
4. Spine rigid.
5. Thigh flexed.
6. When verticals destroy forward inclination of body.
7. Painless.
8. Pain in back.
9. Probing no aid as seeks distant outlets.

Sciatica usually occurs in much older people, and there is no characteristic position, and no deformity except slight flexure. No reflex muscular spasm. Gant says the anterior superior spine of the affected

side is lower than the opposite one. Ashhurst says the prognosis is usually fatal though slow.

Treatment.—Having never seen any positive cases in the very early stages of the disease I have had no experience with the methods of rest, of extension, Benjamin-Lee girdle around the pelvis for limiting motion at the joint, or the Hutchinson high shoe on the well foot, with crutches, and a lead sole on the affected side, but theoretically would prefer that rest of the joint, however obtained, which would permit the moving about of the patient in preference to steady confinement in bed with anteroposterior leverage hip-splints. In the present light of bacteriology the external cauterizations and moxæ of olden times have been abandoned, but I would not, therefore, presume to deny their occasional efficacy, their acute inflammatory congestions perhaps acting as does a severe trauma. It is a matter of common experience that tubercular joints follow much more frequently the mild than the severe injuries. The intelligent surgeon will, of course, do what is possible toward rendering the constitutional condition normal, and in the absence of extension of the process to the tissues external to the joint would be justified in trying the simpler lines of treatment. When, however, an abscess exists, I believe it is of the utmost importance to the patient to have it opened *secundem artem*, never here allowing Nature to take its course, since, whether it opens in the rectum or opens spontaneously externally, there comes the dreaded mixed infection, which in the past led the surgeons to take so gloomy a view of any operative interference, and furnished statistics of thirty-eight abscess cases and only three recoveries (Van Hook). We now appreciate the danger to be a pus-infection, and with reasonable care can avoid this danger if the case be seen early enough. Even having once started, we can many times check the process by prompt radical measures.

The dearth of any systematic plans of attacking this joint when one comes to search the literature is most surprising, some of quite recent date failing to refer to surgery at all (Stedman). Van Hook has offered the most practically systematic plan dependent upon the location of the abscess. "If posterior, incise over the joint; if anterior, chisel away the posterior inferior spine of the ilium, and reach the anterior surface of the joint by following through the artificial notch." Study of the joint led me to approach the articular surface from without, after loosening the gluteal attachments with the periosteum, by chiseling away an auricular fragment, corresponding in approximate size to the joint within, directly through the ilium. The localization of this area is particularly easy if the posterior margin of the great sciatic notch is taken as a guide, and beginning posteriorly, piece after piece is chipped off to the depth of the joint. The whole anterior surface can soon be exposed, and then as much more as may be found by the softened condition of the tissues to be necessary, while at the same time access is gained to any abscess lying anterior to the joint which can be properly drained. At first blush one might think such an incision would result in the disintegration of the pelvic ring, but if it is remembered that the strongest ligaments of the body hold these structures in contact, and that the articular surface is designed more for permission of motion than for supporting weight, and that clinical experience shows that radical removal of the diseased structures does not cripple while it does cure what heretofore has been considered a tedious but hopeless ailment, one need not hesitate to act. Terillon has twice trephined the ilium for drainage of pelvic abscesses over necrotic bone. In speaking of this subject, König states that Fischer and Rinnée have trephined for drainage, but it does not appear clear whether he means at the joint or through the ilium. He has done so himself. With the articulated pelvis in hand it will be seen that this method I have recommended enables one to expose the whole joint, if necessary, and enables one to reach the anterior surface without injuring important structures, while the supra-articular route of Van Hook does not even then comprehend any access to the bony joint. All that one can glean from literature, with the exception mentioned, is that the abscesses were opened and the joint curetted, but this is not so easily accomplished as written, and I believe I have described the only practicable plan of safe approach to the joint.

CASE I.—Child, aged twelve years, a patient in the Michael Reese Hospital. Preexisting lumbar curvature, Pott's disease. Entered the hospital with an abscess anterior and posterior to the sacroiliac joint. Opening of the posterior abscess showed fecal complication, and exploration showed complete perforation of the sacroiliac joint. Patient hectic, with general amyloid degeneration. Death after six weeks.

CASE II.—P. W., aged fifteen years, referred to me by Dr. Ernst Schmidt. Abscess over crest of the ilium communicating with an abscess anterior to the joint. Exploration of the exterior abscess confirmed the diagnosis of sacroiliac disease. Curetting of the joint and draining of the abscess permitted the boy to return home with a small fistulous tract discharging a small quantity of pus posteriorly. Death six weeks after return home. Uremic convulsions, general amyloid disease.

CASE III.—L. Y., girl, aged fifteen years; referred to me by Dr. Frank Billings. Had had operation of curettement of the joint at the age of thirteen, by

Dr. J. E. Owens. Wound required fourteen months to heal. Second attack, abscess anterior to the joint burst into the rectum. First noticed pain at stool; then had strong septic fever. Posterior abscess was tympanitic. Contents offensive; fever 104° F. Operation of curettement and chiseling out of diseased bone. Wound eighteen months in healing. Weight before operation 87 pounds, at present 122.

CASE IV.—G. X., male, aged eighteen years, of small size; Jewish. Admitted to Michael Reese Hospital in September, 1897. Thinks trouble was caused by driving a delivery wagon for several months. Six months prior to admission he began to have pain in the knee and thigh, and then became lame. Four months after onset of the symptoms he went to the County Hospital. There an incision for suspected ischiorectal abscess was made. No result. Then a large pelvic abscess was drained by an incision through the rectum. Fever then was severe. The boy did not improve and later came to the Michael Reese Hospital. The tumor could be felt over the right iliac joint anteriorly. Slight temperature. Operation of chiseling away an ear-shaped mass of bone, exposing sacroiliac joint, Dr. D. F. Coolidge assisting. Patient discharged, improved, but the wound not completely healed, with instructions for dressings to be made at the dispensary. He returned on May 21, 1898, with pulmonary tuberculosis and a small sinus.

CASE V.—Male, aged thirty-two years. St. Luke's Hospital. Tumor posterior to the joint with a sinus leading to the lower segment of the joint. Chiseling and curetting operation, packing, with recovery.

CASE VI.—Referred to me by Dr. Ridlon for early operation. No tumefaction. Pain indistinct, classical, and negative. Some lateral curvature. Advised the constricting fixation girdle.

THE ETIOLOGY OF YELLOW FEVER.[1]

BY FREDERICK G. NOVY, M.D.,
OF ANN ARBOR, MICH.;
JUNIOR PROFESSOR OF HYGIENE AND PHYSIOLOGICAL CHEMISTRY IN THE UNIVERSITY OF MICHIGAN.

(Continued from page 331.)

III. RELATION OF THE SANARELLI BACILLUS TO THE COLON-TYPHOID GROUP.

In his first memoir Sanarelli calls attention to the fact that the growth of his bacillus on gelatin might at times resemble that of the colon bacillus, and thus give rise to confusion. The marked pleomorphism of the colon colonies, their chestnut-brown color and the characteristic appearance of the colon surface colony would serve to distinguish the colon bacillus from that of Sanarelli. This undoubtedly is true when these organisms are perfectly typical. The colon bacillus, however, can be readily modified when grown for several generations on very alkaline bouillon (40 to 50 c.c. normal NaOH per liter), or when grown on hard fifteen per cent. gelatin. The surface colonies then become circular and raised, but are more opaque then those of Sanarelli.

The Sanarelli organism, in some of its characteristics, resembles the colon bacillus, but on the whole it shows closer affinity to the typhoid bacillus. This relationship can best be seen from the following summary of its cultural properties:

Like the colon bacillus, it gives rise to an acid reaction in litmus-colored media. In special litmus media, where the Eberth bacillus does not change the reaction, the Sanarelli bacillus behaves in like manner. It also gives rise to gas production in glucose and lactose media. It differs from the colon bacillus, but resembles the typhoid bacillus in the following properties:

1. The indol reaction is not given, or but very faintly.
2. Milk is not coagulated.
3. The growth on potato is moist and invisible.
4. It produces no growth in Uschinsky's medium. In this respect it agreed with seven different cultures of the typhoid bacillus. On the other hand, six different colons and the Havelburg bacillus gave excellent growths. This medium is, therefore, as useful as either of the preceding in differentiating typhoid from colon bacteria.
5. It produces no growth in Elsner's medium.
6. Cultures in bouillon of diverse reactions remain cloudy almost indefinitely, and on the surface scarcely any ring or film forms. Occasionally a broken film does form on the surface. The colon bacilli form a ring on the surface, and a more or less broken film; the growth soon settles and leaves a perfectly clear transparent liquid. The bouillon culture of only two out of six different typhoid bacilli became perfectly clear on standing, the remainder were undistinguishable from parallel cultures of the Sanarelli bacillus.
7. In bouillon containing 10 c.c. of normal HCl. per liter, added to the neutralized medium, it gives a very slight growth, and in bouillon containing 20 c.c. of the acid per liter there is no growth whatsoever. The growth of the typhoid bacillus is inhibited in like manner, whereas the colon and Havelburg bacilli will grow quite well in such acid bouillon. In bouillon containing 50 c.c. of normal NaOH per liter the Sanarelli and typhoid bacilli can scarcely develop, whereas the colon bacillus gives a fair growth.
8. On agar containing 10 c.c. of normal HCl. per liter, added to the neutralized medium, the growth at first is very slight with Sanarelli and typhoid bacilli. In about five days it becomes thick, dry,

[1] Read before the Michigan State Medical Society, Detroit, May 6, 1898.

white, and lustrous. No growth develops on agar containing 20 c.c. of the acid. The colon and Havelburg bacilli give good thick, white growth on such agar.

9. On agar containing 20 or 30 c.c. of normal NaOH per liter, added to the neutralized medium, the Sanarelli and typhoid bacilli yield at 39° C. thin transparent growths, indistinguishable one from another. On the other hand, the colon and Havelburg bacilli give on the same media thicker, more opaque growths. The appearance of the Sanarelli bacillus on agar at 16° C. has already been described.

10. On gelatin plates at 16° to 18° C. the Sanarelli and typhoid colonies develop very slowly, and at the end of forty-eight to sixty hours, to the naked eye, they have the same appearance and size. On the other hand, the colon and Havelburg bacilli grow much more rapidly; hence, the colonies are several times larger and opaque, yellowish in appearance. Under these conditions the colon, Emmerich, and Havelburg bacilli form typical crater-like spreading-surface colonies, 2 to 3 mm. in diameter, absolutely indistinguishable. The deep colonies of the colon and typhoid bacteria are circular or roundish, slightly granular, and yellowish in color, whereas the deep colonies of the Sanarelli bacillus are circular, coarsely granular, and dark or black in appearance. The temperature and consistency of the gelatin has much to do with the form of the colonies, as shown in the first part of this paper. The Sanarelli bacillus resembles the typhoid bacillus in the slowness of growth on gelatin, but not to any extent in the form of the colonies.

11. On Stoddart's medium the Sanarelli and typhoid bacilli form an exceedingly thin, almost perfectly transparent growth, which in twenty-four hours covers the entire surface of the medium in a Petri dish. The motile colon bacilli do not, as a rule, diffuse as rapidly, and the growth is considerably thicker and slightly opaque. The non-motile colon, Emmerich, and Havelburg bacilli, merely form large thick colonies in the center of the dish.

It is evident from the preceding that the Sanarelli bacillus is closely related to the typhoid bacillus. Numerous comparisons of these organisms, made under most varied conditions, have shown such marked similarity that one cannot escape the conclusion that the Sanarelli bacillus belongs to the group of typhoid-like bacilli. There is not, however, that perfect similarity, such as is seen between the Havelburg and certain colon bacilli. It is interesting to note that from the first post-mortem made by Sanarelli a pseudo-typhoid bacillus was isolated. From a case of acute yellow atrophy of the liver, Vincent (*Compt. Rend. Soc. Biol.*, p. 462, 1893) isolated a colon bacillus in large numbers, which resembled the typhoid bacillus. It was extremely motile, scarcely fermented lactose, gave no indol reaction, and was said to be moderately pathogenic. The gelatin colonies were discrete and translucid.

In addition to the facts presented above, it may be well to state that, morphologically, the Sanarelli bacillus agrees with the colon and typhoid bacilli. Moreover, from cultures of all three of these organisms, on special media, it is possible to obtain large numbers of what I have designated as giant-whips. Loeffler[1] was the first to observe and photograph these peculiar forms, which he found in cultures of the symptomatic anthrax bacillus on blood-serum. Subsequently (1893), I found these same forms in cultures on agar and blood-serum of a new anaerobic bacillus; also, in malignant edema, in symptomatic anthrax, and in tetanus. These strange forms were also found in the body of guinea-pigs, after inoculation with the first-mentioned organism. Excellent illustrations of these giant-whips were kindly made for me by Pfeiffer of Berlin, and will be found in my paper, *Zeitschrift für Hygiene*, Bd. 17, 209. Sakharoff[2] has met with and figured similar forms, which he obtained from gelatin cultures of the *B. asiaticus*. It is not necessary in this connection to decribe the giant-whips as found in cultures of the Sanarelli, colon, and typhoid bacilli, since they resemble exactly the form described in the papers referred to above. Moreover, at an early date I hope to publish my studies as to the conditions under which these composite, or giant-whips, form.

According to Sanarelli the B. icteroides when grown in bouillon after a few days give rise to characteristic involution forms. These are short filaments bent or twisted, with enlargements at or near the end. At times these are quite abundant, and again may be very rare. These peculiar forms are, however, by no means characteristic of the Sanarelli bacillus. A careful study was made of the involution forms formed in bouillon cultures of the various colon and typhoid bacilli under examination. When these were grown under the same conditions, side by side, with the Sanarelli bacillus, similar forms were observed in all. In some of the typhoid cultures the involutions were more numerous than in others. Similar variation was observed among the several colon bacilli. The cultures of the Emmerich and Havelburg bacilli were especially rich in the long, filamentous, nodular involution forms. The degen-

[1] *Centralblatt für Bakteriologie*, vii, 635, 1890.
[2] *Annales de l'Institut Pasteur*, vii, 550, 1893.

erative forms of the B. icteroides agree therefore with those of the colon-typhoid group.

Another fact which goes to show the relationship of the Sanarelli bacillus to the colon-typhoid group is its resistance to destruction by gaseous disinfectants such as sulphur dioxid and formaldehyd. In the study of the value of these gases for room disinfection which I have made in common with my assistant, Mr. H. H. Waite (MEDICAL NEWS, May 21, 1898), the typhoid, colon, Sanarelli, and Havelburg bacilli were included. In each experiment these organisms were exposed, in duplicate, on silk threads (*S*), muslin squares (*M*), and on cover-glasses (*G*). The specimens were exposed to the action of the gaseous disinfectant in a room having a capacity of 1016 cubic feet (28.3 c.m.) for twenty hours, in open sterile Esmarch dishes. When wet these specimens were invariably disinfected. If, however, they were previously dried at 39° C. for two to three hours, they were less easily destroyed. The cover-glasses with the germs spread on only one side were, as might be expected, disinfected first. The disinfection of the muslin squares in the Havelburg set was undoubtedly due to the fact that these had not dried completely. The following summary of the results obtained with dry specimens is taken from the first three tables in the paper referred to :

		Sulphur 3 lbs.		Sulphur 6 lbs.		Paraform 60 g.		Formalin distillation, 150 c.c.	
Typhoid bacillus.	S.	+	+	+	+	+	+	+	+
	M.	+	+	+	+	+	+	+	+
	G.	O	O	O	O	+	O	O	O
Colon bacillus.	S.	+	+	+	+	+	+	+	+
	M.	+	+	+	+	+	+	+	+
	G.	+	O	O	O	O	O	+	+
Sanarelli.	S.	+	+	+	+	+	+	+	+
	M.	+	+	+	+	+	+	+	+
	G.	+	O	O	O	+	O	+	+
Havelburg.	S.	+	+	+	+	+	+	+	+
	M.	O	O	+	+	+	+	+	+
	G.	O	O	O	O	+	O	+	+

+ =positive growth. O=no growth.

It is evident from the above results that the four organisms possess about the same degrees of resistance to these gaseous disinfectants. This fact, taken in connection with what has been shown above, clearly indicates the relationship of the Sanarelli and Havelburg bacilli to the colon-typhoid group.

This marked degree of resistance of the Sanarelli bacillus is borne out by its behavior to cold. The experiments on this point will be discussed in the last part of this paper.

The foregoing facts demonstrate: first, that the Havelburg bacillus is a non-motile colon bacillus; second, that the Sanarelli bacillus belongs to the typhoid group although, like the colon bacillus, it gives off acid and gaseous products.

IV. RELATION OF THE SANARELLI BACILLUS TO YELLOW FEVER.

In order to obtain a clear understanding of the real relation that this organism bears to yellow fever it is desirable in the first place to present a brief summary of the bacteriological results obtained by Sanarelli in his examination of the human subject. In all thirteen subjects were examined.

CASE I.—Subject died on the sixth day. On post-mortem examination gave seven kinds of bacteria; among these can be mentioned the colon bacillus and a pseudo-typhoid bacillus. The *B. icteroides was absent.*

CASE II.—Subject died on the seventh day. The blood drawn from the finger the evening before death, as well as the blood from the cadaver; also, the spleen, liver, lungs, urine, and bile gave a *"certain quantity" of the B. icteriodes.* In the kidneys and in the tracheal and bronchial secretions it was associated with the colon bacillus. It was not present in the intestinal contents and it is worthy of note that it was in connection with this case the first wherein he found the B. icteroides that Sanarelli arrived at the rather early and very positive conclusion that "the favorable habitat of the microbe of yellow fever is not in the digestive canal."

CASE III.—Subject recovered. On the sixth day of the disease blood was drawn from the finger and was *sterile.* The urine gave cultures of the colon bacillus. *No B. icteroides.*

CASE IV.—Subject recovered. The blood drawn from the finger, as well as hepatic fluid obtained by puncture on the eighth day of the disease remained *sterile.* Similar material drawn on the ninth day gave two kinds of bacteria, *one of which, very rare, was the B. icteroides.*

CASE V.—Subject died on the fifth day. Various bacteria, colon bacilli, and streptococci were present. The kidney alone gave *several colonies of B. icteroides.*

CASE VI.—Subject died on the fourth day. The blood, organs, intestinal and gastric contents gave only the colon bacillus. *No B. icteroides.*

CASE VII.—Subject died sixteen hours after entering the hospital. Urine and bile were sterile. The intestinal and gastric contents contained colon bacilli, streptococci, and diplococci. The tissues contained abundance of streptococci. *No B. icteroides.*

CASE VIII.—Subject died six days after entering the hospital. Blood from the finger as well as hepatic fluid and bile drawn on the second day after entering, or four days before death, gave *pure cultures of the B. icteroides.* This was rare in the blood,

fairly abundant in the hepatic fluid, and very abundant in the bile. On post-mortem examination, made two hours after death, the blood, bile, liver, spleen, kidneys, and urine gave an abundance of B. icteroides associated with staphylococci. The tracheal fluid contained the B. icteroides, colon bacilli, and a torula. The gastric and intestinal contents gave only colon bacilli.

CASE IX.—Subject died in six days. Blood from the finger, and hepatic fluid, drawn the day before death, remained *sterile*. On post-mortem examination of the blood and organs most of the culture media remained *sterile*. A few contained a small bacillus. *One out of six tubes* inoculated with material from the kidney *gave the B. icteroides*. The other five tubes were sterile.

CASE X.—Subject died on the sixth day. Blood from the finger and hepatic fluid drawn eleven hours before death, remained *sterile*. On post-mortem examination, made six hours after death, numerous bacteria were present but *no B. icteroides*.

CASE XI.—Subject died on the eighth day. All the cultures made from the blood, spleen, kidneys, bile, and pericardial fluid were either *sterile* or gave a staphylococcus. The urine gave colon bacilli and staphylococci. Numerous cultures were made from the liver *and all but one remained sterile*. The one tube mentioned received 3 c.c. of *hepatic fluid* and developed a club-shaped bacillus which was assumed to be B. icteroides. On rather forced passage through a rabbit the B. icteroides was eventually obtained. It is evident then that this organism was present in exceedingly small numbers and was feebly virulent; otherwise the body was practically sterile.

CASE XII.—Subject died on the twelfth day. Numerous cultures made with an abundance of material from the blood, liver, bile, spleen, and urine remained *perfectly sterile*. The kidneys gave several colonies of a bacillus resembling that of chicken cholera. Two tubes of agar inoculated with *heart-blood* showed feeble growth in the water of condensation, and it was only after passage through animals, as in Case XI., that it was possible to identify the B. icteroides.

CASE XIII.—Subject died on the eighth day. The bile was sterile. The blood and urine contained a few colon bacilli and staphylococci. The liver contained colon bacilli; *B. icteroides was not found.*

It is evident then that the B. icteroides was found in only *seven out of thirteen cases*, or, in other words, in only 53.8 per cent. According to Sanarelli, the third subject who gave negative results and recovered should be excluded, whereas the fourth, who likewise recovered but gave a positive result is, of course, retained.

As can be easily seen from the preceding summary, in the seven cases where positive results were obtained the B. icteroides was, as a rule, far from being numerous. Thus: Case II., the blood and organs contained the B. icteroides in "certain quantity"; Case IV., the bacillus was very rare in the blood and hepatic fluid; Case V., the kidney only gave several colonies of the B. icteroides; Case VIII., gave abundant growth of the B. icteroides; Case IX., the kidney only, and then but one out of six tubes, gave a culture of the bacillus; Case XI., of the numerous cultures made from the liver (and other organs) all were sterile but one, and that gave an atypical growth of the B. icteroides; Case XII., of the numerous cultures from various organs all were sterile, and only the heart-blood gave an atypical growth of the B. icteroides.

It is evident that, in addition to the very low percentage of cases of yellow fever in which it is found, the B. icteroides is, as a rule, present in very small numbers. *In only Cases II. and VIII. can there be said to be an abundant growth. In the remaining cases the bacillus was present in only one organ, and then in mere traces.*

In the recent report of Pothier (*Jour. Amer. Med. Assoc.*, p. 884, April 16, 1898) on the results of the bacteriological examination of presumably fifty-one cases of yellow fever at the Isolation Hospital at New Orleans, it would seem that he has been able to find the B. icteroides in but *three cases.*

It can truly be said that in no infectious disease where the cause has been demonstrated can the specific organism be found in such a small percentage of cases, and in such small numbers as has been shown to be the case for the B. icteroides.

Sanarelli recognizes this serious defect in his work, and endeavors to explain why it is not present more often and in greater number. Two reasons are deduced. First, the bacillus multiplies very little during the disease, and a small amount of toxin can produce severe symptoms of the disease. Second, the toxin, directly or indirectly, by the lesions it produces facilitates secondary infection. Of these two propositions the first is of the most importance. In five out of seven cases where the bacillus was present it was found in extremely small numbers. The assumption that it produces a very powerful toxin, as in diphtheria or tetanus, would, if confirmed, assist in explaining this anomaly. Is it true, however, that the bacillus produces a powerful toxin?

In his second memoir Sanarelli deals especially with the effects of the toxin, which was prepared by filtering through porcelain ordinary bouillon cultures 15- to 20-days old. Of this filtered liquid 15 to 20 c.c. are necessary in order to kill guinea-pigs in 24 hours. Smaller doses, 2–5–10 c.c., decrease the weight temporarily, but the animal recovers. Ten c.c. or more are necessary intravenously to kill rabbits in 7 to 8 days. In one experiment made

by me 10 c.c. of the filtered culture 4-days old killed a rabbit weighing 1770 gr. in 11 days, whereas 20 c.c. of an 8-day culture killed in about half a day. Similar filtered cultures of the Havelburg bacillus proved even more deadly than those of B. icteroides. In dogs 5 to 10 c.c. injected subcutaneously produced local tumefactions, and "even in large quantity is absolutely incapable of producing the characteristic symptoms of yellow fever." With living cultures Sanarelli claims (*loc. cit.*, p. 501) to produce in dogs the symptoms and principal lesions of yellow fever, and yet the supposed powerful toxin is incapable of producing such symptoms in these same animals. Intravenous injections, as might be expected, are more powerful, and may produce vomiting and diarrhea, but the animal soon recovers if the dose is moderate. A larger dose of the toxin, 150 to 200 c.c., will kill the animal! When such enormous quantities must be injected to produce death it is useless to speak about a powerful toxin. And as far as the vomiting and diarrhea of dogs is concerned, after injection of living or filtered cultures, these symptoms afford no support in establishing the presumed etiological relation of B. icteroides. These symptoms, vomiting and diarrhea, are observed in dogs when injected with most any colon bacillus or with the filtered products.

The goat appears to be much more susceptible to the toxin, since death was caused in one instance when 37 c.c. were injected subcutaneously in seven doses within eighteen days. Strange to say, however, in this very susceptible animal the bacteriological examination was negative. That is to say, the toxin did not assist secondary infection as Sanarelli would expect.

It should be noted in passing that Sanarelli at times employed bouillon cultures sterilized with ether. These are said to be more powerful than when filtered. Ether itself sometimes contains highly toxic substances which can be easily demonstrated by allowing a few hundred c.c. to evaporate and then injecting the residual liquid into a guinea-pig. Death may result in an hour or two with most powerful pathologic changes. Ether should not be employed for animal experiments where injections are practised unless it is known to be free from this poison. Cultures of the Sanarelli bacillus sterilized at 57 to 58° F. are less active than filtered cultures.

Not content with the inoculation of toxin into common animals, Sanarelli resorted to experiments on the human subject. These experiments were not published in the *Annales de l'Institut Pasteur*, and I should have made no reference to these were it not that they have been published *in extenso* in the *Annales d'Igiene Sperimentale*, vol. 7, 1897, and have been freely mentioned in American and English journals.

Two subjects received respectively 2 and 5 c.c. of the filtered toxin subcutaneously. Apart from painful, local swelling, some depression, and lack of appetite, no further results were obtained. The most powerful effects, however, followed the intravenous injection of 10 c.c. of the toxin. Incessant vomiting, complete anuria, delirium, and coma were the result; 5 c.c. intravenously in another subject produced likewise very serious results. A fifth subject was not so susceptible and was given 44 c.c. in four injections in eleven days.

Sanarelli sees in these experiments a perfect demonstration of the relation of his bacillus to yellow fever. To a critical observer his conclusion is not justifiable. Nothing is stated concerning the physical condition of the subjects and the presumption is that they were hospital patients. It is a well-known fact that an animal once subjected to a disease, an infection, or an intoxication, is vastly more susceptible than a healthy organism to subsequent inoculation with a poison. Roux and Martin,[1] for instance, observed that a horse which had received three injections of the pneumococcus of Fraenkel was extremely susceptible, even after the lapse of a year, to the diphtheria toxin (½–1 c.c.). An animal once acted upon by any microbic poison, even though apparently fully recovered, is much more sensitive than a new animal. During the past year I have had numerous demonstrations of this very important fact. Owing to the scarcity of guinea-pigs, I was obliged to use a second time animals which had been inoculated with the diphtheria toxin, or with various bacteria from water, cheese, etc. Although a considerable time had elapsed after the first injection, and the animals had apparently fully recovered, yet when inoculated with the B. icteroides they would invariably die in from twelve to eighteen hours, whereas the time for healthy guinea-pigs, according to Sanarelli, ranges from three to six days. Tuberculous guinea-pigs likewise proved to be exceedingly susceptible to the Sanarelli bacilli.

The reaction of the tuberculin in tuberculous animals likewise constitutes an illustration of what has been said. Blood-serum in itself is certainly non-poisonous, and yet instances are known where the injection of diphtheria antitoxin has been followed by speedy death. This is not due to any poison in the antitoxin, nor is it necessarily due to so-called idiosyncrasy. The organism has been weakened by the action of the diphtheria poison and becomes, therefore, exceedingly susceptible to an otherwise harmless substance. Guinea-pigs that have survived

[1] *Annales de l'Institut Pasteur*, 8, p. 617, 1894.

injections of diphtheria toxin and apparently have fully recovered, will frequently die within an hour after an intraperitoneal injection of 2 or more c.c. of normal serum of man and other animals.

It is evident, therefore, that the weakened conditions of the patients at the time of the injection had more to do with the profound symptoms observed than the toxin introduced. The feebleness of the toxin is seen when subcutaneous injections were practised; and, also, in the fifth case. Moreover, it should be borne in mind that we know nothing about the results in man following intravenous injections of the filtered products of even the most common bacteria. What would be the results in man following intravenous injections of micrococcus prodigiosus, colon bacillus, Eberth bacillus, etc.? In all probability such injections would bring about very serious results, especially in previously diseased individuals.

The conclusion, then, which forces itself upon us, is that Sanarelli's experiments on man have absolutely no practical value and do not prove the existence of a powerful poison nor its fancied relation to yellow fever.

There is still further evidence which goes to show that the B. icteroides does not create a powerful poison. It certainly elaborates poisons within the cell, as in the case of the colon bacillus, vibrio of Asiatic cholera, etc., but this poison does not readily diffuse into the surrounding medium. If the filtered culture contained an active toxin, it should, on injection into an animal, eventually yield an *antitoxic* serum. Through the kindness of Dr. McClintock of the biological department of Parke, Davis & Co., subcutaneous and intravenous injections of the filtered cultures of the B. icteroides were made into a horse. The animal received in the space of five months 974 c.c. of the toxin intravenously and subcutaneously. The serum of that animal has no more value than normal rabbit-serum in preventing infection with the Sanarelli bacillus. The failure, then, to obtain a distinctly antitoxic serum confirms the conclusion arrived at above, namely, that B. icteroides does not produce an active, soluble toxin.

In a recent number of the "Public Health Reports" of the United States Marine Hospital (April 15, 1898, p. 371) there is a statement quoted from Sanarelli that he has been unable to obtain antitoxic serum, and that when injections of cultures were made the serum was bactericidal, not antitoxic. This is in line with the fundamental researches of Roux, Metschnikov, and Salimbeni on immunity against the cholera vibrio. The above acknowledgment places Sanarelli's serum beside the anticolon, antityphoid, and Pfeiffer's anticholera serums. The results obtained by Sanarelli in the treatment of yellow fever with this serum are exactly what might be expected. Of thirty patients treated, ten died, a mortality of thirty-three per cent.[1] The mortality in yellow fever is subject to very great variation. During the recent epidemic in New Orleans it was about eleven per cent. In South America it undoubtedly does rise at times to forty or fifty per cent.

The second reason presented by Sanarelli, in order to explain the difficulty of finding the B. icteroides in the body, was that the specific toxin of the yellow-fever microbe, by its action on the organs, favored secondary infections. The colon bacilli, staphylococci, and streptococci thus introduced, are supposed to outgrow, or even suppress, the B. icteroides, and thus create the difficulty in detecting this organism. In guinea-pigs and rabbits inoculated with B. icteroides the blood and internal organs almost invariably contain pure cultures of this bacillus. In these animals apparently the toxin does not exert this favoring action. Sanarelli himself recognizes this fact. In the goat referred to, which died after repeated injections of the toxin, there was likewise no secondary infection.

In looking over the summary of results obtained by Sanarelli in his examination of yellow-fever subjects it should be noticed that the blood from the finger, and the hepatic fluid were sterile in Cases III., IV. (eighth day), and IX. In Cases IX., XI., and XII., the internal organs were practically sterile and yet in each of these cases the B. icteroides was found in only one tube out of a large number that were inoculated. According to Pothier the blood of eight out of ten yellow-fever patients was sterile.

Undoubtedly it is true that in yellow fever, as in nearly all infectious diseases, secondary invasion is likely to occur, and may be expected, as the result of the action of the specific poison. This invasion, as pointed out above, is by no means constant in yellow fever, and consequently does not constitute a sufficient explanation of the failure to find the germ in not more than 53.8 per cent. of the cases, nor does it explain the small number of the B. icteroides present in most of these cases.

In order to detect the B. icteroides in the internal organs of man, Sanarelli employs a method which is open to serious objection. In view of the fact that the bacillus occurs in small numbers, its detection in tissues is said to be difficult. To facilitate its detection in the several organs, these are first washed with mercuric chlorid and suspended in an incubator

[1] Since the above was written Sanarelli has published a fourth paper (*Annales de l'Institut Pasteur*, p. 348, May, 1898). The statement is made that the mortality was 27 per cent. in 22 cases treated. In the paper 31 cases are described, with a mortality of 32 per cent.

at 39° C. for twelve hours. Under these conditions the organisms present multiplied so that on subsequent sectioning and staining groups of bacteria could be readily demonstrated. Sanarelli assumes that the groups of bacteria thus demonstrated are those of B. icteroides. This is a mere assumption, since any colon bacillus that might be present would give rise under those conditions to exactly the same groups, and the individuals comprising these could not be distinguished from B. icteroides.

Pieces of the liver, kidney, and spleen from Case II. were thus treated and are figured in Plate XII. of Sanarelli's memoir. It is of interest to note that in the description of this case the kidneys are expressly said to contain the B. icteroides associated with the colon bacillus (*loc. cit.*, p. 442). May not, therefore, the group of bacilli shown in Fig. 4, Plate XII., consist of colon bacilli? No definite statement is made regarding the presence of colon bacilli in the spleen or liver, but it is quite reasonable to assume, being present in the kidney, that they were likewise present in the other two organs. Consequently conclusions based upon such methods of work cannot be received with much confidence.

It follows from what has been said that Sanarelli has failed to comply with the first rule of Koch as to the constant presence of this organism in yellow fever. In the action of the pure cultures of the B. icteroides on animals, Sanarelli claims to obtain the final proof of the relation of this organism to the disease. These results, however, are not above question and have no more actual value than the toxin experiments already referred to. According to Sanarelli, the injection of B. icteroides in guinea-pigs produces a cyclic disease which cannot, as a rule, be influenced by the amount of the injected culture. That is to say, the animals usually die in from five to eight days regardless of the dose employed. This cyclic character, on which so much stress is laid by Sanarelli, is by no means constant.

After repeated passage through collodium sacs, employing the method of Roux, Metschnikov, and Salimbeni, it is possible to obtain twenty-four-hour bouillon cultures of this organism which, injected intraperitoneally into guinea-pigs in doses of 1 c.c. as a rule, will prove fatal in less than eighteen hours. The sac method of exalting the virulence of this organism is not necessary, however, to accomplish this result. Vigorous cultures, obtained by frequent transplantation, will give exactly the same result. Consequently, the so-called cyclic character is manifested only by cultures that have already been weakened. Whether the guinea-pig dies early or late the heart-blood and internal organs contain pure cultures of the organism. There is an entire absence of secondary infection. In this respect, as well as in its "cyclic" character, B. icteroides resembles the bacillus of hog-cholera.

The experiments on rabbits are of special importance because of the pathological alterations produced, especially in the liver and kidneys, by this organism. Fatty degeneration of the liver can easily be demonstrated. Moreover, the kidneys show marked inflammatory changes in the glomeruli and in the cells of the tubules. Albumin, and hyalin to epithelial casts, may be found in the urine. These results, it should be remembered, are by no means characteristic of this organism. There is scarcely an infectious disease in man in which some fatty degeneration of the liver and nephritis do not occur. In general, it may be said that infections and intoxications lead to fatty degeneration and to nephritis. These results can be obtained in a number of experimental diseases, even in more pronounced form than with B. icteroides. Thus, a rabbit received a subcutaneous injection of a mixture of three different colon bacilli and died in four days. Neither one of these by itself would under like conditions produce fatal results. The urine contained albumin and casts. The liver showed numerous white spots. On hardening in Flemming's solution and subsequent staining with safranin, exquisite fatty degeneration was demonstrated. In these sections the fat globules were more abundant than in the liver of a rabbit after inoculation with B. icteroides (Sanarelli, Plate XIV., Fig. 2). Sections of the kidney showed marked parenchymatous degeneration. The tubules were frequently filled with detritus, and in many cases the cells were completely loosened. In the above experiment then, as was expected, the same degenerations were obtained, even more pronounced than with the Sanarelli bacillus. No special importance, therefore, can be attached to the experiments of Sanarelli on rabbits.

According to Sanarelli, the dog is the best animal for reproducing the lesions and symptoms of yellow fever. It should be noted at the beginning, however, that the dog is not very susceptible, and hence it is necessary to introduce relatively large doses of the virus by intravenous injection. The marked fatty degeneration of the liver and of the kidney is considered by him as proof positive of the identity of the experimental disease with the yellow fever of man. The vomiting, diarrhea, and icterus were regarded as additional, conclusive evidence of this relationship.

These results might be considered of value if control experiments with other organisms had given negative results. There is no evidence, however, to show that Sanarelli made any comparative trials with other related organisms. Proper controls, in

this and other experiments, would have prevented error. In the first place, the above-mentioned symptoms, vomiting, diarrhea, etc., are produced in dogs as a result of various injections. I have met with these symptoms frequently in dogs after the injection of bacteria found in cheese, milk, etc. Of special importance in this connection are Emmerich's experiments on dogs with B. Neapolitanus (*loc. cit.*, p. 342).—A dog which received a subcutaneous injection of this colon bacillus reacted with frequent vomiting and profuse diarrhea. In three days it lost 450 gr. in weight, and was so weak that it could not stand up. A monkey likewise reacted to Emmerich's bacillus with diarrhea and vomiting, coma, and death.

Not only can certain bacteria, such as the colon bacillus, induce vomiting and diarrhea, but as pointed out above they can induce exquisite fatty degenerations. In cats, Emmerich observed marked fatty degeneration of the kidney. Fatty degeneration of the liver and kidneys can, therefore, be brought about by various organisms.

A third fact observed by Sanarelli in his experiments on dogs was that the gastro-intestinal mucous membrane was often altered and showed hemorrhagic infiltrations. Similar alterations have been described by Emmerich in cats, dogs, and monkeys. Other organisms can induce like infiltrations, as Sanarelli himself indicates.

From the above it is evident that Sanarelli's bacillus produces in experimental animals a disease not unlike that following colon infection. The symptoms and pathological lesions, therefore, do not establish an identity between that disease and yellow fever. From the evidence thus far adduced it is clear that the B. icteroides is not proven to be the cause of yellow fever. From the facts which follow it will be seen that this organism cannot be the cause of this disease.

Agglutination.—The behavior of the Sanarelli bacillus to serum was given a careful, thorough study. The microscopical examination of hanging drops of serum, inoculated with the various organisms, was always resorted to in studying this phenomenon. Where dilutions were employed these were made by adding to a drop of serum, 10, 20, 30 drops, etc., respectively, of distilled water by means of a drawn-out tube pipette. The inoculations were made from agar cultures grown for 20–24 hours at 39°C. The first specimen tested was an antipest horse serum. This, when undiluted, gave prompt and complete agglutination in less than 15 minutes. Another pest serum behaved in a similar manner. A normal horse serum produced excellent agglutination in half an hour. Subsequently a large number of specimens of serum from various sources were examined. The serums of fifteen horses immunized against diphtheria, tetanus, and colon bacillus invariably agglutinated the Sanarelli bacillus in less than one hour when undiluted. In dilution of 1–10 most of these produced agglutination within 2 hours. In dilution of 1–20 less than one-half produced light agglutination within 2 hours. The undiluted serum of normal guinea-pigs likewise produced prompt agglutination. As a rule, the agglutination ceases with a dilution of 1–10, but in several instances good agglutination was obtained at 1–20 and even at 1–30. The serum of guinea-pigs infected with Sanarelli's bacillus shows no quantitative difference when drawn immediately after death, and compared with the serum of the same animal drawn just before inoculation. Normal rabbit serum behaved in exactly the same manner as guinea-pig serum. The blood of seven normal persons and of one sarcoma patient were likewise examined. When undiluted, each one of these agglutinated the Sanarelli bacillus in less than one hour. In dilutions of 1–10 a slight agglutination was given in the same time.

In general it may be said that the serum of healthy men and animals will promptly agglutinate the Sanarelli bacillus. Such serum will give a more or less marked reaction even when diluted with ten parts of water. On further dilution, as a rule, agglutination does not take place.

These results are at variance to some extent, and serve to explain certain results obtained by Sanarelli. These differences are probably due to the fact that Sanarelli has employed the macroscopic method, adding the serum to bouillon cultures in a test-tube, and observing whether or not a deposit formed. This procedure is very defective, and it is not to be compared in accuracy with the microscopic method described above. According to Sanarelli the blood of yellow-fever cadavers possesses a variable power of agglutination. The blood of a convalescing yellow-fever patient induced very slow agglutination. An antidiphtheric serum produced a very rapid, whereas antityphoid serum brought about a partial, agglutination. He further states that the normal blood of man and of many other animals does not induce the phenomenon of agglutination (*loc. cit.*, p. 755). The experiments detailed above effectually disprove this assertion.

Sanarelli in his experiments on men injected with the filtered cultures of his bacillus[1] notes that the serum in the third and fourth case, in a dilution of 1–5, gave a precipitate of the bacillus in twelve hours. The serum of the fifth subject, in a dilution of 1–10, gave complete precipitation in two hours at 37° C., "as if it were the serum of a vaccinated ani-

[1] *Annali d'Igiene Sperimentale*, 7, p. 445, 447, 449.

mal." With reference to these cases Sanarelli arrives at the rather forced conclusion that they represented classical types of yellow fever, and that the fifth case corresponded to repeated typical attacks of abortive yellow fever.

As a matter of fact, as stated above, normal serum of man and animals will cause agglutination in the dilutions mentioned above, and even at times in greater dilutions. The serum-tests in the above-mentioned experiments on man then do not support the interpretation that the intoxication induced was that of yellow fever.

It has been suggested (Lerch) that the agglutination of the Sanarelli bacillus by the serum of yellow-fever patients was of diagnostic value. The fact that normal serum, even when diluted, yields agglutination effectually disproves this statement.

In the preceding part of this paper it has been shown that the Sanarelli bacillus agrees with the colon, typhoid, and Havelburg bacilli in its resistance to destruction by gaseous disinfectants. Experiments with mercuric chlorid, carbolic acid, and lysol have likewise shown that the B. icteroides is a relatively resistant organism. This fact is still further emphasized by the following experiments which it will be seen effectually disprove the claim of its causal relation to yellow fever. It is a well known fact that yellow fever is exclusively a disease of the warm countries. It cannot gain a permanent foothold in the United States, for the simple reason that cold stops its ravages. The first good, sharp frost effectually puts an end to an epidemic of yellow fever. Cold, then, is a most effective and reliable agent for destroying the yellow-fever microbe. To accomplish this end extreme cold is not necessary. The Sanarelli bacillus will not grow at zero° C. Tubes of bouillon, agar, and gelatin, inoculated with this organism and kept immersed in melting ice for two weeks, showed no sign of growth. At the end of that time when placed in the incubator they promptly developed, and these cultures were as pathogenic to guinea-pigs as normal cultures. Even when kept for a month at zero degree the resultant cultures were fatal as usual to guinea-pigs.

The minimum temperature at which the B. icteroides will grow is about 10° C. Agar and bouillon cultures were allowed to develop at this temperature in an ice-chest, and were then left there for five months. In other words, they were kept for five months at a temperature of 10° to 15°C. At the end of that time these cultures were transplanted to bouillon. One c.c. of this new culture developed for 36 hours at 39° C., injected intraperitoneally into a large guinea-pig produced death in 6 days. Evidently no attenuation had taken place, and yet under these conditions one would expect to meet with a weakened yellow-fever germ. On November 29th cultures of the Sanarelli bacillus were placed outside the window, and allowed to remain there for fifteen days. The average minimum temperature for that period was 26.4° F. (−3.6° C.), and the average maximum temperature was 36° F. (2.2° C.). At the end of this period the germs grew as well as before, and their virulence was not diminished.

The following experiment is of still more importance. Agar cultures of the B. icteroides were placed outside of the window for three days during very cold weather. During the first day the temperature ranged from −2° to −13° C. The temperature on the second day ranged from −10° to −20° C., and on the third day from 0° to −15° C. It should be said that most of the time during these three days the temperature was below −10° C. At the end of the first, second, and third days transplantations into bouillon were made. These bouillon cultures were developed for 36 to 40 hours at 39° C., and the resultant growths were in every respect normal. Each culture injected intraperitoneally into new guinea-pigs in doses of 1 c.c. produced death in from 18 to 20 hours.

This last experiment may be considered as a crucial test of the relation of the Sanarelli bacillus to yellow fever. Freezing for three days at a temperature below −10° C. had absolutely no effect on the virulence of this organism. As pointed out above, epidemics of yellow fever are promptly brought to an end by a sharp frost. In other words, the microbe of yellow fever is exceedingly sensitive to cold. This certainly cannot be said to be the case with the Sanarelli bacillus. This organism in its behavior to cold again shows that it is related to the colon-typhoid group. If, therefore, the Sanarelli bacillus were the cause of yellow fever we would expect to find this disease, like typhoid fever, distributed the length and breadth of the American continent regardless of climatic conditions.

The conclusions arrived at in this study can be briefly summarized:

1. The Havelburg and Sanarelli bacilli are distinct.

2. The Havelburg bacillus belongs to the colon group.

3. The Sanarelli bacillus undoubtedly belongs to the typhoid group.

4. Neither the Havelburg nor the Sanarelli bacillus is the cause of yellow fever.

The etiology of yellow fever is yet to be worked out. The microbes of Havelburg and Sanarelli are to be placed in the already long list of disproved causes. The negative bacteriological results, taken

in connection with the epidemiological facts observed in this disease, would seem to indicate that the cause will not be found in our group of bacteria. It is more than likely that the germ of yellow fever, as well as those of smallpox, measles, hydrophobia, etc., belongs to a group of organisms, smaller than our bacteria, and as yet unknown, awaiting discovery. The recent work of Roux and Nocard on the microbe of pleuropneumonia already proves the existence of organisms smaller than the "infinitely small" bacteria.

HYGIENIC LABORATORY, UNIVERSITY OF MICHIGAN.

WAR ARTICLE.

THE INVASION OF PORTO RICO FROM A MEDICAL STANDPOINT.

BY NICHOLAS SENN, M.D.,
LIEUTENANT-COLONEL, U. S. V., CHIEF OF THE OPERATING STAFF WITH THE ARMY IN THE FIELD.

THE occupation of Cuba and the Philippine Islands by our conquering navy and army in such rapid succession seemed to increase the desire of conquest and opportunities to test the strength of our arms. With the destruction of the weak navy of our enemy there was nothing in the way of sending troops to any of the many Spanish possessions. The fall of the heroic Cervera and his faithful little band off the harbor of Santiago before the murderous fire of our well-equipped fleet cleared the pathways of the ocean of further sources of danger. It was but natural that the beautiful island of Porto Rico, one of Spain's most valuable possessions, should have been selected by the military authorities as the next objective point for contention. Repeated attacks by our navy on its best stronghold, San Juan, had failed to bring about surrender and to give a foothold on Porto-Rican soil. So far the navy had taken the lead in bringing Spain to terms and the army was anxious to do its share in wresting from its greedy grasp another enslaved people. Major-General Miles, who conducted the invasion in person, decided to march upon San Juan from several directions, and after uniting the forces attack the city jointly. The experience gained in Cuba had taught us an important lesson in conducting the Porto-Rican campaign. General Miles laid his plans wisely and with special reference to gain the desired object with as little suffering and loss of life as possible. Every movement in this campaign was made with a due regard for the welfare and success of our troops rather than a desire for personal gain and aggrandizement which characterized the Cuban campaign as every one knows. He was well aware of the depressing effects of the tropical climate on the unseasoned troops and of the necessity of resorting to timely and efficient precautions in preventing disease. From experience and personal observation he recognized the fact that the unavoidable privations incident to war are multiplied many times when the seat of war is a strange and remote country which presents a climate and environments unfamiliar to the invading force. His actions were clean-cut admissions that he was in need of a medical advisor and that they were influenced by the frequent consultations held with the chief surgeon. The war in Porto Rico was conducted upon the most humane principles, and although no great battles were fought, victory upon victory followed the footsteps of our army and in less than three weeks our flag floated over three of the largest cities of the island. Our troops love and respect their leader and have followed him without fear and grumbling under the scorching sun, full of confidence and trust.

The news that an armistice had been declared reached the headquarters at Ponce, August 14th, and the troops are now resting on their arms awaiting the final adjustment of the terms of peace. Eager to fight, yet every soldier in the field received this message of peace with joy and enthusiasm, fully satisfied that the army had done justice to the flag and country it represents. Colonel Charles R. Greenleaf, chief surgeon of the army in the field, accompanied General Miles on his trip from Guantanamo to Porto Rico and has been with the army ever since. He was long enough in Cuba to gain a full insight into the horrors created by infectious diseases which so constantly follow large armies, especially in a war of invasion. He was amazed when he saw to what extent yellow fever had broken out during the few weeks the troops had been in Cuba. There was no difficulty in tracing the disease to a total lack of precaution on the part of the general in command. Colonel Greenleaf had given his advice and directions before the army left Tampa, but they were not heeded. Owing to want of cooperation on the part of General Shafter the medical officers found themselves powerless in preventing and combating the dreaded disease. Colonel Greenleaf's prompt and energetic action on his arrival in Cuba did much in suppressing the disease, but it was too late to guard against a general outbreak. The many recent graves in Cuba containing the remains of the victims of this disease are the best proof of what will happen when the leader of an army ignores the health and comfort of his men. In planning the Porto-Rican invasion General Miles availed himself of the invaluable services of his chief surgeon. The expedition was well equipped with medicines, hospital stores, and medical officers to meet all possible emergencies. The result has been that the army has been so far singularly exempt from disease with the exception of typhoid fever and the effects of heat, both beyond the control of medical officers. Since his arrival in Ponce Colonel Greenleaf has been the busiest man in the army. He has not been content in simply issuing his orders from headquarters, but he has attended in person to the execution of every detail. He has visited the camps, the hospitals, and exercised personal oversight over the distribution of hospital supplies, instruments, and medicines. Anxious to serve the sick and wounded, impatient when face to face with a slow, hesitating subordinate, he has more than once performed temporarily the duties of an ordinary hospital steward to furnish a much needed object lesson. His work justifies the confidence imposed when he was appointed to the high and responsible position he holds.

FIRST SKIRMISH.

General Miles landed with his expedition, which included a number of war-vessels, at Guanico, Monday, July 25th. The harbor was entered by the now famous little gunboat "Gloucester," under the command of Lieutenant-Commander Wainwright. A landing was effected by thirty sailors, the Spanish flag was hauled down and the Stars and Stripes raised amid the cheers of the sailors who knew well that what they had just witnessed meant liberty and freedom for the down-trodden people of the island of which they had just taken possession. The planting of the flag and the deafening cheers which reechoed from the hills of the liberated island were followed by a volley from the hidden enemy, which was promptly responded to by the guns of the "Gloucester" and a Colt rapid-fire gun which had been taken ashore. The Spaniards fled in confusion and sought shelter among the adjacent hills, leaving four killed on the field, while our soldiers escaped without a scratch.

The turn of the infantry came soon after landing in the form of a lively skirmish in which we lost one killed and fifteen wounded, of whom one died a day or two later. Most of the injuries were flesh wounds which healed in a remarkably short time. A very interesting incident occurred during this skirmish. The day was hot and our troops had to ascend a steep hill from the crest of which the Spaniards defended themselves. One of the volunteer soldiers, outrunning his comrades, advanced far ahead of his line, and when he had nearly reached the Spanish position was overcome by heat. He fell in a semi-unconscious state. A Spanish doctor rushed to his aid with a stretcher and two hospital-corps men, administered the necessary restorative, and had him conveyed at once within our line. This one act alone goes to show that the Spaniards have often been unjustly accused of being cruel and inhuman. This certainly has not been the case during the present war. From my own observations I am sure that they have respected the Red Cross. In fact the Red-Cross people of Porto Rico, composed largely of Spaniards, have shown the greatest activity and interest in their humane work during the entire campaign. If anything, they have rather been over zealous, judging from the number of insignia displayed and worn. It was a common thing to see men wearing a white cap with an immense red cross on top, another one in front, besides the brassard. Ponce was taken and occupied without any resistance whatever. The citizens received our soldiers with enthusiasm and manifestations of joy. General Miles was hailed as a long-looked for friend rather than a conqueror.

The next engagement occurred between Arroyo and Guayama, between a small Spanish force in ambush and General Haines' brigade, and resulted in eleven wounded on our side. The only death following this skirmish was that of a soldier of the Third Illinois Infantry who was shot accidentally by an unknown man of the Fourth Pennsylvania Regiment. The bullet caused an extensive non-penetrating injury of the chest from the effects of which he died next day. Such accidents have occurred too often during the present war and to prevent repetition in the future this matter should be investigated, as was done in this instance, by the proper authorities. Among the injured was a man who was shot through the pelvis, and another one the subject of a gunshot wound of the elbow-joint, both of them doing well a few days later when I examined the wounded in the Brigade Hospital at Guayama. The third skirmish took place between the advance column of General Wilson's Division on the march to San Juan and a small Spanish force entrenched on the summit of a high and steep hill. Lieutenant Haines, the son of General Haines, was the only one who was brought on board the "Relief" August 14th. One of the wounded was operated on by Dr. Parkhill in an ambulance. The abdomen was torn open by a fragment of a shell, the intestines protruded, and a resection had to be made of a loop for a tearing injury. It was reported that the patient rallied well from the immediate effects of the operation and that hopes were entertained of his recovery. Another engagement took place between the troops under command of General Schwan on their way from Ponce to Mayaguez and about 1000 Spaniards ambushed four miles from the latter city. The fight resulted in two killed and eighteen wounded on our side. All of the wounded were brought on board the hospital ship "Relief," which called at Mayaguez on her way to New York August 15th.

Such is a brief account of the casualities sustained by our army during the Porto-Rican campaign. The experience here coincided with that gained in Cuba to the extent of confirming the humane nature of the modern weapon. The proportion of killed to wounded is even smaller than in the Cuban war, as well as the number of seriously injured. Thanks to the more elaborate preparations for the campaign the wounded received prompt and efficient attention. The suffering of the well, sick, and wounded cannot be compared with what I saw in Cuba. War is a great educator and should we again be called upon to invade a foreign country, we shall profit by the experience of the past.

TYPHOID FEVER IN PORTO RICO.

The native doctors in Ponce, Porto Rico, gave us the assurance that not a single case of yellow fever had been seen in that city for the last three years. We were informed that in San Juan isolated cases occur from time to time. Malaria is prevalent in all the valleys, more especially in and around Ponce. The large pendulous abdomens and the pale faces of the many little naked children in city and country are the best witnesses in showing the prevalence of malarial intoxication. Typhoid fever is endemic in certain localities, but at present Ponce is almost free from this disease. Having seen the destruction of life and the indescribable suffering caused by yellow fever in Cuba, Colonel Greenleaf naturally turned his attention toward protecting our troops in Porto Rico against this scourge. The proximity of Porto Rico to Cuba, and the many possible sources of infection made such a course imperative. That this fear was not unfounded, and that the chief surgeon recognized the danger, and made use of

timely precautions are best shown by the contents of a letter addressed to the Adjutant-General, Headquarters of the Army, and Circular No. 1 issued before the army sailed from Guantanamo to Porto Rico, and a copy of the quarantine regulations formulated at the same time.

Headquarters of the Army,
On Board the U. S. S. "Yale," en route
to Porto Rico, July 23, 1898.

To the Adjutant-General, Headquarters of the Army.

SIR: I have the honor to submit the following recommendations for the prevention, as far as possible, of the introduction of yellow fever into the command now about to land on the island of Porto Rico:

The assignment of an officer of rank, to be placed in command of the base of supplies, with authority to indicate the sites to be occupied by the various supply-depots and the hospital, and to enforce the regulations governing the health of the attachés of these departments and the persons who may visit them on business.

The assignment of a sanitary inspector whose duty it shall be to examine all vessels and persons arriving at our base from seaward ports, and to prepare sanitary regulations for the government of all transportation and persons arriving and departing from stations by land. The officer should have authority to quarantine all suspected persons and means of transportation, and to disinfect their belongings either by fire or by such other means as may be deemed necessary.

All persons connected with the army are forbidden to enter any building whatever on the island without express authority from these headquarters, and all buildings in rural districts that may be suspected of harboring the germs of disease should be destroyed by fire or otherwise disinfected.

As woven goods, particularly those of woolen fabric, are special carriers of disease, the purchase or acceptance of articles of this kind from stores or inhabitants of the island is strictly forbidden. Any such property found within the lines will be at once destroyed and the holder subject to punishment.

That the commanders of regiments be instructed to prepare their camping-grounds with great care and maintain a rigid police in them; under no circumstances shall they camp on ground that has previously been occupied either by troops or collective bodies of the inhabitants.

That medical officers be required to make frequent inspections of the commands to which they belong and that any suspicious case of fever be immediately isolated and the fact of its occurrence reported to these headquarters.

Canteens should be filled daily with tea or coffee, and these beverages used habitually instead of water, unless that has been previously boiled.

Very respectfully,
CHARLES R. GREENLEAF,
Colonel, Assistant Surgeon-General, U. S. A., Chief Surgeon, Army in the Field.

Headquarters of the Army, Office of the Chief Surgeon, On Board U. S. S. "Yale," en route to Porto Rico, July 24, 1898.

Circular No. 1.

1. Medical officers will, upon receipt of this circular, report to the chief surgeon of the army the number of medical officers, hospital stewards, acting hospital stewards and privates of the hospital corps on duty with their command. Also the number of ambulances, litters, and tents, and if medical supplies are insufficient, note the general character needed. This report will be made on the enclosed form:

2. A field hospital will be organized at the army base as soon as possible after landing, and a depot of supplies will be connected with it. As we are widely separated from our source of supplies a strict economy in their use is necessary; surgeons of divisions and brigades will give their personal attention to this important subject.

3. Extreme vigilance is enjoined upon medical officers in the matter of camp sanitation, errors in this particular being promptly reported to the respective commanding officers.

4. The experience at Santiago has demonstrated the efficiency of properly applied first dressings in gunshot wounds; these should be left untouched until the patient arrives at the base hospital, unless the condition of the wound absolutely demands a redressing en route from the first-dressing station. All diagnosis tags will be marked "Dressing not to be removed," or "Redressing required," as the condition demands. Unless an imperative necessity exists, surgical operation will not be attempted at the front.

CHAS. R. GREENLEAF,
Colonel, Assistant Surgeon-General, U. S. A., Chief Surgeon, Army in the Field.

QUARANTINE REGULATIONS FOR THE BASE OF MILITARY EXPEDITION TO PORTO RICO.

1. Every vessel shall be officially visited by the inspector before communication is made with other vessels or the shore.

2. A vessel having yellow fever or smallpox on board shall not be allowed to communicate with the shore, or with other vessels, but shall leave the island.

3. Vessels coming from sources of infection shall be detained five days without communicating either with the shore or with other vessels. If at the expiration of this time no cases of fever shall have developed, landing may be made under the following precautions:

All fomites shall be disinfected by one of the following methods: Immersion for one hour in 1-1000 solution of bichlorid; sulphur fumigation in a chamber 24 hours, four pounds of sulphur being used for each 1000 cubic feet of space, or boiling half an hour with complete immersion. The following need not be disinfected unless directly exposed to infection:

All new and dry material unpacked, all iron and steel implements, all goods in new and original packages not having been broken or packed in an infected locality. Goods other than textile contained in textile material, such as coffee in sacks, bacons, spices, etc., kept dry, and not broken in an infected locality, do not require disinfection other than the container, which shall be treated as fomites as above. Fruits, sound, unless exposed in an infected locality, need no disinfection. Live stock may be admitted.

Such ships shall be thoroughly cleansed and disinfected by the free use of 1–1000 solution of bichlorid, and by fumigation with sulphur before they may again receive men or supplies.

Ships quarantined shall display the usual flag, and those in detention shall be visited by the inspector daily until the time of quarantine shall have expired.

4. Vessels carrying passengers or having fomites from localities of infection, though they (the vessels) may hail from healthy ports, shall be subject to the same quarantine restrictions as vessels known to hail from infected localities.

5. Due precaution shall be taken to prevent infection of the base of supplies through communicating with infected localities along the line of march, by teamsters, and others. As far as possible they should not be allowed to remain at the base longer than necessary to load and unload, nor to come in such contact as to communicate infection. Stragglers, prisoners, and strangers should be immediately sent away.

CHARLES R. GREENLEAF,
Colonel, Assistant-Surgeon General, United States Army; Chief Surgeon, Army in the Field.

Major Woodbury was appointed sanitary inspector. He met with the hearty cooperation of the city authorities of Ponce in the performance of his onerous and often unpleasant duties. The sanitary condition of the city underwent a great improvement in a few days. The water-supply was found satisfactory. The absence of a sewerage system threw many obstacles in the way. The appearance of smallpox in a village some distance from Ponce made vaccination necessary among the soldiers and natives who were not protected against the disease. An abundant supply of vaccine virus was on hand, and was at once issued and used. When I arrived at Ponce, August 7th, I found typhoid fever raging to an alarming extent. It was desirable to trace the origin of the disease. The absence of typhoid fever during this season of the year, its outbreak in all the commands, and the short time that had intervened between leaving the United States and the landing in Porto Rico, made it probable that the disease could be traced to the infected camps occupied by the troops before leaving for Porto Rico. General Miles was very anxious to obtain reliable information regarding the origin and spread of this disease. Pursuant to the following order I made an extensive and systematic investigation:

Headquarters of the Army,
Office of Chief Surgeon, Port Ponce, Porto Rico,
August 11, 1898.

Lieutenant-Colonel Nicholas Senn, Surgeon, U. S. V., Chief of Operating Staff of the Army.

SIR: You will proceed to the town of Ponce, visit the military and other hospitals of that town, and such of the camps in its vicinity as you may deem necessary, for the purpose of investigating and, if possible, determining the cause of typhoid and other fevers now prevailing in the army, and report the result of your investigation in writing to me. Should you find it necessary to have the services of an interpreter, or other civilian to aid in your work, you are hereby authorized to employ him, sending the bill to this office for payment.

Very respectfully,
CHARLES R. GREENLEAF,
Colonel, Assistant Surgeon-General, U. S. A., Chief Surgeon, Army in the Field.

I obtained accurate information of two hundred fever patients, of which number 90 per cent. were well marked typhoid fever, the balance malaria and the result of sunstroke. I estimated the number of fever patients in Ponce and in the immediate vicinity at 250. In extending my inquiries to General Brook's command, with headquarters at Guayama, I found about 145 additional cases; however, in that locality malaria seemed to predominate. Most of the patients came from Chickamauga by way of Charleston and Newport News. The Second and Third Wisconsin Regiments furnished the largest contingent. Almost every soldier in the different hospitals belonging to either of these regiments suffered from typical typhoid fever, and what attracted my attention was that the disease appeared to be of a more serious type than in most of the men belonging to other regiments. The locality from which these regiments came, when encamped at Chickamauga, must have been badly infected.

As the result of my investigation, I reported to Colonel Greenleaf the number of cases found, and that in my opinion the disease was contracted in every instance before leaving the camps in the United States. In view of the fact that most of the cases came from Chickamauga I suggested at the same time that the Medical Department should recommend immediate evacuation of that camp. In Ponce most of the patients found shelter and care in the Spanish Military Hospital, then in charge of Major Ten Eyck, U. S. A. The Club House and a school for girls of the Sisters of Charity were also placed at the disposal of the chief surgeon and were soon filled with patients. Miss Chanler of New York did excellent service as a nurse in the former temporary hospital. A congestion which occurred in the Military Hospital, and which could not be prevented, took place when General Wilson's Division moved forward and unloaded at the door all of the sick in the Division Hospital, some 150 in number. The overcrowded condition was remedied the next day when a large number of the more gravely ill were sent on board the "Relief," anchored in the harbor of Ponce. Medical supplies were in abundance at all times and were freely issued without any formality. The "Relief," and later the yacht "May," brought an abundant supply, with many delicacies for the sick. Milk was bought and freely supplied to the sick. It was the intention of the chief surgeon to establish an extensive outdoor receiving hospital as soon as the tentage arrives, which, according to information received from the Surgeon-General, was then on the way. The number of new cases of typhoid fever in the Porto-Rican army will probably be a limited one, as the victims of this disease were immediately separated from their comrades, and if the troops are recalled as soon as the treaty of peace has been signed we need entertain little fear of the indigenous spread of the disease.

CLINICAL MEMORANDA.

SIMPLE TALIPES EQUINUS.

BY JAMES K. YOUNG, M.D.,
OF PHILADELPHIA;
PROFESSOR OF ORTHOPEDIC SURGERY IN THE PHILADELPHIA POLYCLINIC; CLINICAL PROFESSOR OF ORTHOPEDIC SURGERY IN THE WOMAN'S MEDICAL COLLEGE, ETC.

IT is a fact well known to surgeons generally that simple forms of clubfoot are rare, the compound forms predominating. The first two cases here recorded are interesting on account of the patients having presented themselves within a day of each other, on account of their rarity, and, the first case, because primitive equinus is so rare that Tamplin discredits its congenital origin entirely, not having seen a case. To these are added three cases which were seen previously.

The relative frequency of simple equinus, taken from a large number of cases which were treated in the Orthopedic Dispensary of the University Hospital, is found to be as follows: Acquired equinus 16 per cent.; congenital equinus 2 per cent.

CASE I.—W. H. K., white, male, aged eight years. Had the ordinary diseases of childhood. Family history negative. Labor was not instrumental. Upon examination marked pes equinus was found, which had existed since birth; the heel of the right foot was two inches from the ground. The child also had internal strabismus. The operation was performed on the day of admission, the Achilles tendon being divided and a plaster-of-Paris cast applied with the foot in an over-corrected position. The application of an apparatus was not found necessary.

CASE II.—E. S., white, female, aged three years and eight months. No family history of interest. One and one-half years before the child came under observation she had an attack of infantile paralysis which resulted in a partial paralysis of the muscles of the left leg. Upon examination a limp was seen on the affected side and the muscles were slightly atrophied; the circumference of the left calf was 8½ inches, of the right 8¼ inches. The diagnosis of simple equinus was apparent. The Achilles tendon was divided and the usual plaster-of-Paris dressing applied with the foot at a right angle, this not being over corrected because it was a palsy and not a congenital case. The after treatment prescribed was massage and electricity, to be followed by an ankle brace with equinus stop.

CASE III.—S. N., white, female, aged seven years. At two years of age she had had infantile paralysis. When first seen there was contraction of the Achilles tendon and slight atrophy of the leg, with measurements as follows: Length of right limb, 23⅝ inches; of left limb, 24 inches; circumference of right thigh at 3 inches, 11¼ inches; of left thigh at 3 inches, 12¾ inches; circumference of right thigh at 7 inches, 14¾ inches; of left thigh at 7 inches, 15½ inches; of right calf, 10 inches; of left calf, 10⅛ inches. Right dorsal scoliosis was also present. Tenotomy was performed, followed by the application of a shoe to which ⅜ inches of cork was added inside. This was followed by massage and electricity, which increased the size of the part. The recovery was perfect and the child walked without a limp.

CASE IV.—F. G., white, female, aged eight years. Family history negative. Labor was normal. Had a hemiplegia in early childhood. When the case came under observation the hemiplegia was still present, the arm being atrophied and contracted. The leg measurements were as follows: Length of right leg, 27 inches; of left leg, 26½ inches. The foot was in equinus position and the patient walked with a decided limp. An attempt was made to correct the deformity by mechanical stretching, but without success, after which a tenotomy of the Achilles tendon was performed. This was followed by the use of a shoe elevated with a half inch of cork inside and an ankle support with an equinus stop.

CASE V.—E. T., white, female, aged eight years, of good ancestry. Labor was difficult and the child was delivered with forceps. The present deformity occurred at two years of age and consisted of a right hemiplegia. When the case came under observation June 22, 1898, the arm had recovered but the deformity of the lower extremity was still present. There was contraction of the Achilles tendon, the heel being raised 1½ inches from the ground. There was slight atrophy of the right leg, the circumference of the right calf being 9½ inches, and that of the left 9⅞ inches. Tenotomy of the Achilles tendon was performed and this was followed by the adjustment of an ankle brace with equinus stop.

These cases, when properly treated, give the most satisfactory results of all orthopedic cases, and in many instances the deformity is not only corrected, but the disposition of the child is improved.

APPENDICITIS IN A CHILD. SARCOMA OF THE HUMERUS. TUBERCULOSIS OF THE RIGHT KIDNEY AND URETER.

BY WILLIAM D. HAMILTON, M.D.,
OF COLUMBUS, OHIO.

CASE I. *Appendicitis in a Child.*—Edna D., aged nine years, was brought to Mt. Carmel Hospital by Dr. Callinan of Corning, April 7, 1896. Forty-eight hours previously she had been taken with general abdominal pain and vomiting. On the day before her admission her physician first saw her. He diagnosed appendicitis and advised operation. Her condition upon admission was as follows: She was well nourished, but evidently very sick. Her cheeks were highly flushed, pulse 138, and temperature 100° F. Some tympanites; irregular and modified dulness over the entire right half of abdomen, with extreme tenderness. She had vomited dark-green material during the day. She evidently had suppurative peritonitis. The right lower segment of the abdomen was most tender.

Ether was given, and after the parts had been cleansed an incision was made over McBurney's point. In making the section the infiltrated abdominal walls were suggestive of pus, which, upon entering the cavity, was found external to the cecum. It was at once evident that the fluid was not walled off by adhesions; that there was pus in the loin and in the pelvis as well, and that she had a

general purulent peritonitis. A median incision was made opposite the cul-de-sac, and more pus was found. The appendix could be felt overlapping the external iliac vessels and dipping into the pelvis. Although but eight minutes had been spent, including that in irrigation, she was suffering from shock. It was, therefore, deemed wise to insert gauze drains, and to allow the operation to remain incomplete. Strands of gauze were inserted from the loin to the opening in the groin; also, from the cul-de-sac through to the lower angle of the median incision. Several ounces of pus had been evacuated. The next week she was better. On April 18th, however, she complained of pain and tenderness in the loin, and had fever. She was again etherized and a counter opening made in the right loin, which allowed the escape of the lumbar accumulation.

On May 9th a third operation was performed. The openings previously made were explored for the appendix. It had originally been located on the brim of the pelvis. It was finally found in the loin, outside of the colon, buried in a mass of adhesions, from which it was with difficulty enucleated. It contained a concretion. Although one hour was consumed in the operation there was no shock. Her convalescence was uneventful. She is now in perfect health.

CASE II. *Sarcoma of the Humerus.*—A. L. F., a farmer, aged forty-two years, a resident of Arblia, Union County, Ohio, entered the hospital April 23, 1896. His family history was good, no case of malignant disease having occurred. He had had good health. He stated that in June, 1895, he strained his right arm in lifting. He supposed that the bone was "cracked" at the time of the accident, although he used the member with some discomfort until November, 1895. In that month, however, when using an ax, the humerus broke spontaneously at the middle. Since then the member had been useless. He could make some movements below the wrist, but few if any above that point. A fusiform, rather solid enlargement of the arm, involving the upper half, reached nearly to the shoulder. A hypodermic needle having been driven into the growth, an ounce of dark-colored, bloody serum was withdrawn.

A diagnosis of malignant disease, probably sarcoma, was made, and an operation performed on May 1st. In order to minimize hemorrhage it was thought best to ligate the subclavian artery in its third portion. A tourniquet could not be applied as there was no room for it. Amputation was performed at the shoulder-joint above the diseased portion of bone. The loss of blood was very slight, and there was no shock. The patient made a prompt recovery, has increased in weight and strength, and is enjoying excellent health.

The specimen was afterward examined and was found to be a sarcoma. The growth was as large as two fists. For two-thirds of its length the humerus had disappeared. Spicula of bone could be seen in the substance of the growth.

CASE III. *Tuberculosis of the Right Kidney and Ureter.*—The patient, an unmarried woman, aged twenty-three years, was referred to me by Dr. Robert Shannon of Piqua, Ohio. There was no history of tuberculosis in her family. She had been healthy until a few months previously, when she was taken sick with a disturbance of the bladder. She had fever and frequent and painful micturition. She had lost about fifteen pounds in weight. Soon after her illness began catheterization was necessary on account of retention. The urine was drawn three or four times a day. Pus was always present. A fortnight before her admission to the hospital vesical irrigation was frequently carried out, but without benefit. After admission she voided her urine every few minutes. She was unable to sleep. A urinalysis at this time showed it to be alkalin and free from sugar. Its specific gravity was 1028, and pus was present in large amount. No tubercle bacilli could be found then or subsequently. Cystoscopy by my colleague, Dr. Charles S. Hamilton, by the Kelly method, showed that the base of the bladder was inflamed and red, and at one point at the base of the organ it bled rather readily. The right ureter was thickened and was palpable through the vagina for a distance of three inches. During ether anesthesia, the right kidney, somewhat enlarged and slightly movable, could be felt in the loin. On two subsequent occasions, once without ether, cystoscopy was repeated, the last time on November 25, 1896, when redness of the base of the bladder in the ureteral region, with occasional areas where the normal glaze of the bladder was absent, was noted. The region of the right ureteral orifice was reddened more than any other part of the bladder. The left ureter was catheterized and the instrument left in place long enough to collect several ounces of urine, which was subjected to microscopic and chemical examination with negative results, no evidence of disease being found. The patient's appetite was poor. Her heart and lungs were normal. A boggy, tender lump, somewhat larger than a fist, could be felt in the right loin in the region of the kidney. Its size seemed to vary at different times.

A diagnosis of tubercular pyelonephritis, with ureteritis, was made, and an operation performed on December 31, 1896. Ether was given, and a firm pillow placed beneath the left loin. A six-inch incision, from near the last rib, was made obliquely downward and outward to within one and one-half inches of the right anterior superior spine of the ilium. The kidney having been exposed, it was peeled from its fatty capsule. It was movable, and the lower end was larger and evidently distended with pus in such a way as to increase its size one third. The pelvis and vessels were freely exposed, and the kidney delivered onto the surface of the abdomen. The vessels were tied with silk in two parts, leaving a long button after division. The ureter was tied just below the pelvis of the kidney, and touched with carbolic acid. When the ureter was divided a teacupful of urine and pus, curdy in character, escaped and soiled the field of operation somewhat. The usual toilet of the wound was made, and it was partially closed, with iodoform-gauze drainage. The pedicle was tied with strong silk. There was practically no shock. Time, one hour and fifteen minutes. The patient once or twice became very cyanotic as

a result of the anesthesia, and her tongue had to be drawn forward. She was soon convalescent, and her temperature became normal. A few days after the operation some fever resulted from suppuration about the ligated ureter. She gained ten pounds in weight, menstruation, which had been absent during her period of invalidism, returned, and her vesical annoyance was about relieved.

On examination of the removed kidney it was found that the typical appearances of tuberculous pyelitis were present. The pelvis of the ureter was dilated, and coated here and there with miliary tubercles. The ureteral obstruction was evidently caused by dilatation of the pelvis and the resulting atrophy of the renal cortex.

The redness of the bladder seen on cystoscopic examination was considered to be due to the irritating character of the urine discharged from the kidney, and not to tuberculosis of the bladder-wall or mucosa. The patient had suffered from attacks of renal pain when the distention of the kidney with pus and urine was greatest. These attacks were terminated invariably by a free discharge of purulent urine from the bladder. She soon experienced great relief from the dysuria. I would have been inclined, however, to advise removal of the kidney, even though the bladder had shown, *in a mild degree*, the lesions of tuberculosis, on the ground that the kidney was the primary focus of the disease, and that no amelioration of vesical symptoms could have been expected until the bladder had been freed from the injurious effect of purulent and irritating urine from the diseased kidney. I have seen at least one case in which manifest tuberculosis of the bladder in the female was cured by removal of a tuberculous kidney, the patient being in good health and free from symptoms two years after the operation.

MEDICAL PROGRESS.

Removal of the Saphenous Vein for Chronic Phlebitis.—VIKO (*Jour. Amer. Med. Assoc.*, July 9, 1898) removed, with complete success, the saphenous vein, from the inner malleolus to one inch above the knee, in a case of chronic phlebitis. As a result of this operation, the patient was for the first time in fourteen years freed from swelling, induration, and eczema of the leg, and could walk and stand with comfort. Since this operation gives such good results in varices the writer thinks that it should be equally helpful in chronic phlebitis, where the veins have lost their function anyway, and act only as irritants. Drugs may for a time relieve the eczema, pain, and swelling, but their action is only temporary, while in surgical measures as above described, there is hope of a speedy and complete cure.

Results of Treatment with Superheated Air. — REED (*Philadelphia Polyclinic*, August 6, 1898) gives some of the results obtained in a year's use of the Sprague Hot Air Therapeutic Apparatus. Not only were patients benefited who suffered from rheumatism and gout, but the success of this treatment in bronchial and asthmatic difficulties, in tonsillitis, conjunctivitis, and many nerve troubles was abundantly demonstrated. Hot air proved itself a sovereign remedy for sprains, bruises, and synovial effusions. In gout, even if tophi have formed, they may still sometimes be softened and discharged through the excretory organs, as the skin and kidneys are stimulated by the hot blood, and circulation is restored to the affected part. Sleep returns to the sleepless, and the general economy is rejuvenated. Sciatica of some months' standing, lumbago, and torticollis were sometimes cured in one application, as were lobar pneumonia and pleurisy. Rheumatoid arthritis was treated with varying success. The soreness and general symptoms were generally relieved, but often the stiffness of the joints remained in spite of repeated applications. In all cases where persistent efforts were made, the progress of the disease was checked. Altogether Reed had at his command records of 1400 applications of high degrees of heat, in a great variety of affections, and from the study of these cases he is well satisfied that the use of superheated air is capable of a wide application in medicine, and will help in the better understanding of lithemic affections. When the nature of the malady was such that the body of the patient was placed in the apparatus, the heat employed was from 250°–260° F. If the arm or leg was placed in the cylinder, the air baths were often given at a temperature of from 300°–350° F. Any apparatus which will not give as high a temperature as this must be of limited service.

Traumatic Suppurative Splenitis.—CROMWELL (*Maryland Med. Jour.*, August 13, 1898) was called to see a strong and healthy girl, aged seventeen years, who to avoid being caught in a shower had run a mile to her home. During the last part of this run she had a severe pain in her left side, but did not stop for it, and the pain subsided of itself some minutes after she had reached the house. It recurred the next day and become more severe. Two days later an examination revealed a tumefaction on the left side of the abdomen and above it a deep sulcus, which the patient said was caused by the band of her petticoat, it being very tight. The patient could obtain a degree of comfort by lying continuously on her right side. Iodin and blisters proving of no avail in reducing the inflammation, an incision was made through the abdominal parieties, and into the substance of the inflamed spleen, and a great deal of blood, followed by pus escaped. The flow of pus continued for several days under the influence of emollient poultices, and after it ceased there was a flow of serum lasting several days longer. The total discharge of blood-pus and serum was estimated at thirty ounces. The girl made a perfect recovery.

Piperidin as a Uric-Acid Solvent.—TUNNICLIFFE and ROSENHEIM (*Lancet*, July 23, 1898), who, some time since, called attention to the solubility in water of piperidin urate, have more recently been conducting investigations in order to see if this remarkable property of piperidin can be utilized in medicine. Their plan was to study the subject from (1) a chemical and pharmacological, and (2) a clinical point of view. The first part of their research has been completed, and the report has been presented

under the following heads: I. Chemistry. II. Conditions which must be filled by any drug to justify its therapeutic use in the uric acid diathesis, including under this head gout. (*a*) Proof of the non-poisonous nature of the drug in doses equivalent to those in which it would have hypothetically to be administered; (*b*) the demonstration of the drug as such in the urine; (*c*) the property of dissolving (1) uric acid (on the distal side of the excreting membrane of the kidney), (2) urinary sediment, and (3) sodium biurate in the blood. Under *c* a comparison is given between the power of piperidin and that of other known uric-acid solvents.

This outline gives an idea of the scope of the report. The conclusions stated in the words of the writers are as follows:

"1. Tartrate of piperidin may be safely given to a man in doses of 15 grains (1 gram) three times a day or oftener, in uric-acid gravel and in gout.

"2. Taking all the conditions into account, this substance is preferable to any other drug up to the present introduced for this purpose, having the additional advantage of being sufficiently cheap to render it within the reach of every one.

"3. Lysidin, piperazin, and urotropin all have an influence in increasing the solvent power of serum for sodium biurate and urine for uratic deposit in varying proportions, but to a less extent than piperidin."

These experiments, so far as they have gone in this direction, tend to show that all these substances diminish the total amount of uric acid excreted, but not the total amount of nitrogen. This fact seems to indicate that these substances have a double action, in that, although capable of acting as uric-acid solvents, they also exert an influence upon metabolism.

The close relationship between the constitution of uric acid and xanthin bases renders it possible that under the influence of these reducing agents (to which class uric-acid solvents mostly belong) uric acid is in the body transformed into xanthin or its immediate allies. This reduction has recently been accomplished in the laboratory with the help of formic acid, chloroform, and potassic hydrate.

An Unusual Complete Rupture of the Aorta.—Ashwin (*Lancet*, July 9, 1898) reports a case of complete rupture of the aorta occurring in a man aged fifty-six years, in which life was prolonged for more than five hours after the break took place. The patient was walking quietly on level ground when he fell suddenly. He was unconscious, and was at once carried into a hospital. He was in a state of profound collapse, from which he did not recover, though he twice vomited matter without special characteristics. He was thought to have suffered from cerebral hemorrhage. The examination made after death showed that the pericardium contained about six ounces of freshly coagulated blood, and that the aorta was torn clear across about three-fourths of an inch above the semilunar valves, and that the pericardium covering the vessel had been stripped up as far as the origin of the innominate artery. This lesion, and a further most remarkable one by which the lumen of the torn vessel was kept patent, explained the length of life after so serious an accident. This was an invagination of the distal ruptured end into the transverse portion of the arch. The intima of the invaginated portion looked inward, not outward, and it was not evident how this could be possible until the invagination was reduced. Then it was seen that the ruptured end of the vessel had been turned inward and passed through a rent in the wall of the aorta just below the origin of the innominate. A second invagination had taken place, the end of the vessel being again turned inward, and passed through a second rent in its own wall a little nearer to the heart than the preceding one. By this means the lumen of the distal portion of the ruptured aorta was preserved, so that the blood which escaped from the upper end of the vessel into the pericardial sac could continue its course into the descending aorta. No explanation of this unusual invagination is offered. Any one may reproduce it by taking a soft rubber-tube of large lumen and cutting two holes in the opposite sides, distant about two and three inches respectively from one end. Then disregarding the hole nearest the end of the tube, invaginate the end of the tube as far as the second hole, pulling it out through this hole. Next invaginate into itself the end of the tube which protrudes through this hole, causing the end of the tube to pass through the hole nearest the end into the lumen of the non-invaginated portion of the tube. The lumen of the tube will thus be reestablished, but imagination fails to depict how this could take place in the living aorta. There were no lesions of the cardiac valves, and only a slight hypertrophy of the left ventricle, and several small atheromatous patches in the aorta.

The Role of Clothing in the Causation of Disease.—Goldschmidt (*Therap. Monatshefte*, July, 1898) says that too little attention is paid to the effect of clothing in producing disease and of causing symptoms in those already ill. The weight of the clothing is often a serious load for an invalid, and the effect of perspiration is to increase the weight sometimes as much as threefold, this depending on the nature of the material, etc. In phthisical and rachitic individuals, in whom the sweat is so profuse, such an increase of weight may mean a great deal. The evil effects which other patients may suffer from uncomfortable corsets, tight collars, stocking supporters, and leather shoes are fully treated of by the author. Local pressure is a disadvantage, though a general even pressure may, in some instances, be a help to recovery, as illustrated by the benefit obtained in ulcer of the leg from an even elastic bandage. Friction from the clothing is a further subject for consideration. If upon the sensitive parts of the body, for instance the genitals, this may produce nervous symptoms, or it may develop or retard the cure of an eczema, etc. The effect of different kinds of clothing is different in this respect, just as the fibers of cotton, wool, and linen vary in harshness, conductibility for heat, and in the ability to absorb moisture. The color of the clothing and the weave of the goods must also be considered in reference to the conditions under which it is to be worn if one desires to give really intelligent advice as to its fitness.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

THE ARMY INVESTIGATION.

THE vigorous and persistent demand of the country for an official inquiry into the causes of the alleged neglect, mismanagement, and consequent suffering of our soldiers has finally drawn from President McKinley an order for an investigation. Technically, and as a matter of formality, this order came in answer to a report from Secretary Alger. Surgeon-General Sternberg saw the necessity for this weeks ago and promptly placed on file a petition for a Court of Inquiry. Had this request been acted upon immediately some conclusion might have been reached in time to be of service in ameliorating the condition of some of the transports and rendering service to the army in Porto Rico.

It is well, however, that the investigation is to be prosecuted now. The proposition of the President is broad in its scope and prescribes an examination into the conduct of the commissary, quartermaster, and medical bureaus of the War Department during the war, and into the extent, causes, and treatment of sickness in the field and in the camps. The investigation will, therefore, cover the entire conduct of the war and probe to the bottom all the charges of neglect and inefficiency that have been made. The personnel of the committee of investigation, as already outlined, gives promise of most thorough, impartial, and searching work. The pressing need of the hour and the work that will be productive of immediate beneficial results is indicated in the last part of the President's pronunciamento and has reference to the extent, the causes, and the treatment of sickness in the camps. Active operations in the field are at an end, but the Volunteer camps will be continued for a year or two, and some more efficient means must be devised and enforced to keep them free from disease than has obtained during the past few months. To discover, apprehend, and punish those who have been responsible for the neglect and suffering of our soldiers in Cuba and on the transports may be important as a warning in the future, but the immediate health of the troops in camp is a far more urgent cause of anxiety. The discovery of the cause of disease and the establishment of such sanitary and hygienic regulations as shall protect and preserve the health of the Volunteer Army is the demand of the hour.

IODOFORM IN LOCAL TUBERCULOSIS.

LOCAL tuberculosis occupies a place in surgical pathology that astonishes the surgeon himself when he looks over his case-book at the end of a year and finds what a high percentage of his cases have come under that category. If he is in attendance at a children's hospital this percentage mounts to a very high figure. The surgery of tuberculosis, however, is not confined to the use of the scalpel, curette, and bone-chisel, since one of the most decided advances along this line is the positive demonstration that *iodoform* is curative when brought in contact with tuberculous tissue. This fact has led to its extensive use as an injection into all tuberculous areas and its value is far greater than the average practitioner realizes. Tuberculous joints need not always be excised, caries of the spine is most beneficially influenced by iodoform, and cold abscess in any part of the body should be treated by this method before open operation is suggested.

Billroth and Mikulicz were among the first to propose the injection of such cavities with a ten-percent. solution of iodoform, and the following repre-

sents the accepted method of procedure at the present day: The tuberculous abscess or joint cavity is first tapped under strict aseptic precautions with a large trocar and the semi-fluid contents and tissue fragments withdrawn. The cavity is then thoroughly irrigated with sterile-water, and a ten-per-cent. mixture of iodoform in glycerin injected through the trocar to a full distention of the cavity. The filled cavity or joint is then manipulated to bring the iodoform solution in contact with every interstice of its interior. A gradual absorption of the glycerin leaves powdered iodoform in direct contact with every part of the tuberculous lining membrane. The cavity usually refills and the process must be repeated two or three times at intervals of a few weeks before a cure is effected. The iodoform appears to cause a breaking down of tuberculous membrane lining such a cavity, the underlying tissues are stimulated to throw out granulations which help to soften and throw off the membrane, and the cavity eventually cicatrizes. Normal cartilage in a joint is unchanged by the iodoform and the amount of motion regained in such a joint will depend upon the extent of the destruction already existing in the articular cartilage.

The best point for puncture in the wrist is just below the styloid process of the ulna, and in the elbow-joint just above the head of the radius. In the hip a point is chosen just above the greater trochanter (the thigh adducted and rotated inward) and the needle thrust directly inward until it strikes the head of the femur. The knee is best tapped on either side beneath the patella, and the ankle beneath the malleoli. Anesthesia is unnecessary in any one of these processes. A joint retains its swelling, as a rule, after the first injection and a slight reaction is present, but with subsequent drainage and injection of the joint at intervals of three or four weeks, the tissues become firmer and the swelling disappears. As a primary measure in all cases of joint tuberculosis this method possesses great value, and in such cases as spinal caries (Pott's disease), where the diseased bone is inaccessible to operation it is invaluable. Of course in those cases of bone tuberculosis where an open operation may remove entirely the diseased area and leave the parts in a condition suitable for permanent cure, operation is to be preferred. Tuberculous sinuses are much benefited and often healed by the use of a ten-per-cent. solution of iodoform in olive oil. The orthopedic surgeon is certainly teaching us two very important facts with regard to local tuberculosis; first, that the condition is amenable to treatment to the degree of perfect cure; and second, that the attainment of this result requires unlimited patience and perseverance.

ECHOES AND NEWS.

Professor Virchow in London.—Professor Virchow will deliver the next Huxley lecture at Charing Cross Hospital, London, in October. It is proposed by the prominent members of the profession of London to extend to him the courtesy of a public dinner at which Lord Lister will preside.

Spanish Prisoners Arrive in Spain.—The Spanish transport "Satrustoqui" is reported as having arrived at Santander, Spain, from Santiago with Spanish prisoners. General Lenares, the former commander of the Spanish forces at Santiago, was a passenger. There were eighty-three deaths during the voyage.

The Tri-State Medical Society.—The Tenth Annual Meeting of this Society, consisting of the members of the profession of Alabama, Georgia, and Tennessee, will be held at Birmingham, Ala., Tuesday, Wednesday, and Thursday, October 25, 26, and 27, 1898. Dr. Frank Trester Smith of Chattanooga, Tenn., is the secretary.

Alleged Poisoning from Eating Canned Meats.—So common, a few months ago, were the cases of alleged poisoning from eating canned (tinned) meats in London that the London Chamber of Commerce appointed a special committee to investigate the matter. The committee has reported that it invariably found such allegations to be unfounded.

Sick Soldiers at Santiago.—Major Lawton, commanding at Santiago, reports that there are not more than fifty of the Fifth Army Corps now remaining in Cuba who are sick. Two hundred and sixty-one convalescents and others left Santiago last week on the "Vigilancia." She arrived at Montreal September 13th. There were three deaths during the voyage. Sixty men were transferred to hospital.

Dr. Pratt and the Chicago Academy of Medicine.—Dr. James G. Kiernan, the Secretary of the Chicago Academy of Medicine, announces over his signature that the recently issued catalogue of the Chicago College of "Osteopathy" contains the assertion that the "orificialist surgeon," E. H. Pratt, one of its faculty, is a member of the Chicago Academy of Medicine. Dr. Kiernan says that he has never been a member, nor is he eligible.

Americans Killed in Battle.—The official records of the War Department, as far as completed September 6th,

show that during the war with Spain there were 33 officers and 231 enlisted men of the army killed in battle, a total of 264. This number includes all the lives lost in battle in the Philippines as well as those in Cuba and Porto Rico. The percentage of officers killed is strikingly large, and is said to be unprecedented in the battles of the world.

The Denver Meeting of the American Medical Association.—The generous hospitality accorded the members of the Association and invited guests at the meeting in Denver will be long remembered by those who accepted it. It is gratifying to know that after all bills, including the subscription of $2000 to the Rush Monument Fund, had been paid by the local committee of arrangements, something over $4000 remained in the hands of the committee and was returned *pro rata* to the subscribers to the entertainment.

Yellow Fever in Mississippi.—Surgeon Carter of the Marine Hospital Service has reported that the total number of yellow-fever cases which have appeared at Orwood, Miss., is thirty-five but as yet there has been no death. The disease has been traced from Orwood to Taylor, a small town in northern Mississippi, where five cases were reported on July 20th. Two of the persons affected afterward moved to Orwood and from this the disease is believed to have been propagated. The disease is mild in type and no fears are entertained that it will become serious in character.

The Sectional Addresses of the British Medical Association.—In commenting upon these addresses the *Medical Press and Circular* says: "We have been rather painfully impressed in more than one of the addresses at Edinburgh by the somewhat carping, lower-motive attributing, not to say sordid, tone that has been struck by their authors. This was not altogether wanting in that portion of the 'Address on Surgery,' called by the author the moral aspect of the art, or rather of its practice. It was repeated by Dr. Joseph Bell in the children's section, and especially by Dr. McBride, who occupied the chair in the section of laryngology and otology."

The Source of Typhoid Fever at Camp Black.—Colonel Byrne recently appointed to investigate the source of typhoid fever at Camp Black reports that nearly all the typhoid cases there are among the members of the 201st Regiment. The water-supply of this regiment is good; the drainage system of the camp excellent. The source of typhoid infection was obscure until Colonel Byrne discovered that the men had been in the habit of bringing water in pails from a farm well at some distance from the camp, because it was cooler and more palatable than that from the camp hydrants. This well was found to be within twelve feet of a loosely built vault which received the waste of a supposed typhoid-fever patient.

The Return of the Porto-Rican Army.—The transports "Chester" and "Obdam" arrived at New York last week from Porto Rico bearing members of the First Army Corps who were returning home from the Porto-Rican campaign. The "Chester" brought 60 officers and civilians and 1150 men, making a total of 1210. The "Obdam" brought Major-General Miles and his staff, and about 1000 men. All on board were well. On board the "Chester" there was one death during the voyage, that of Captain M. H. Smith, Company K, Fourth Pennsylvania. Six men were in the ship's hospital, five suffering from typhoid fever and the other from malaria. The University of Pennsylvania Hospital sent a special train from Philadelphia to New York to meet the "Chester" and transport immediately to its wards as many of the Pennsylvania Regiment as required hospital care.

Vaccination and the Queen's Speech.—The absence of any reference to the new Vaccination Act in the Speech from the Throne on the closing of Parliament is by no means without its significance. Her Majesty's example in matters affecting the health of her people has always been in the direction of encouraging everything which science and practice have proved to be of real benefit to them, and in no matter has the example been more marked than in the advocacy of vaccination as the real preventive of smallpox. When Parliament was opened the Vaccination Bill was announced by the Queen to the Houses of Parliament and through them to her people. The Bill has passed in a form which causes deep anxiety to a large portion of the more intelligent classes, and in dissolving Parliament no reference is made to it by her Majesty. It is well known that the preparation of the Queen's Speech is no mere matter of form which is delegated to her ministers. Hence the significance of the omission.—*Lancet.*

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

THE HOSPITAL SHIP "RELIEF" — DR. KEEN AS A MEMBER OF THE WAR-INQUIRY COMMISSION — PERSONAL NOTES—HEALTH-BOARD NOTES.

PHILADELPHIA, September 15, 1898.

THE United States hospital ship "Relief" arrived here from Porto Rico last Monday evening having on board 244 sick soldiers. Four who died of typhoid fever on the way were buried at sea, and with this exception all the men stood the voyage remarkably well. An opportunity to inspect the ship was offered as she lay here twenty-four hours, and all who availed themselves of the chance were struck with her cleanliness, and the perfect arrangements which existed for the care of her passengers.

The "Relief" is an entirely new double-deck passenger steamer built at Chester, Pa., in 1896, for passenger traffic between New York and Portland. The decks are divided into four wards—No. 1, occupied by the officers, on the upper deck forward; No. 2, the upper deck, aft; No. 3, the lower deck, forward, and No. 4, the lower deck, aft; these are painted white throughout, with the exception of the floors, which are a chocolate-brown color. On each side of the wards are "double-deck" iron bedsteads, arranged end to end, and extend-

ing the length of the wards, which can accommodate about 250 men comfortably.

Throughout the entire ship the effects of perfect sanitation and good nursing were apparent in the splendid condition of the men and their contentment and enthusiasm for doctors and nurses; "hospital odor" was conspicuous by its absence, a fact largely commented on by veteran army men and it was indeed hard to realize that the "Relief" was a hospital ship so clean and sweet was she from stem to stern.

The hospital staff consisted of Major George H. Torney, U. S. A., who was in command; Major Alfred E. Bradley, U. S. A.; Major Francis Metcalf, U. S. V., and Acting Assistant-Surgeons John Howland, Ernest Schultz, Clarence McWilliams, and Charles E. Morrow. There were three hospital stewards, twenty privates of the hospital corps, ten men, graduate Bellevue nurses, and ten trained women nurses from New York and Philadelphia hospitals, and four acting hospital stewards.

Director Riter and Dr. Hughes met the "Relief" at the pier with ambulances, police patrol wagons, and delivery wagons fitted up with cots, the sick being assigned as follows: Pennsylvania Hospital, 84; Jefferson Hospital, 38; Polyclinic Hospital, 25; Medico-Chirurgical and Presbyterian, 24 each, and the University Hospital, 21.

Great pleasure is felt in Philadelphia that the President should have invited Dr. W. W. Keen to be the medical man of the War-Inquiry Commission. Dr. Keen, though an undergraduate, acted as Assistant Surgeon with the late Dr. Samuel Gross during the Civil War at the Army Hospital, then stationed near the site of the present Philadelphia Hospital, obtaining his diploma at the close of the war. Whether Dr. Keen's duties as Professor of Surgery at Jefferson Medical College and his own practice will prevent his acceptance or not it is impossible to say, but he seems to be an ideal man for the place.

Dr. John Ashhurst, who earlier in the summer was seriously ill at his summer place in Overbrook, is now convalescent.

Dr. Howard F. Hansell has returned from a tour of Canada and Dr. Francis X. Dercum from a tour of Europe.

Dr. Daniel E. Hughes, chief resident physician of the Philadelphia Hospital, has been appointed Acting Assistant-Surgeon, U. S. A., with instructions to look after and arrange for the distribution of returning sick soldiers to the various city hospitals.

Major Edward Martin, Surgeon, U. S. V., returned with the Third Regiment this week.

Henry Trimble, Professor of Analytic Chemistry in the Philadelphia College of Pharmacy and editor-in-chief of the *American Journal of Pharmacy*, died August 24th. Another death of last month was that of Dr. Richard Holmes Townsend, one of the oldest physicians in Philadelphia. He was born in 1817 and after graduating from Jefferson Medical College began practising here, retiring about twenty years ago.

Dr. Henry C. Boenning, State Quarantine Physician, has written Governor Hastings suggesting that, as many sick soldiers will return to this city by water, as many be received at the quarantine station at Marcus' Hook as can be accommodated.

The Board of Health has sent copies of the following resolution to all the hospitals of this city:

Resolved, that the managers of the hospitals in Philadelphia be requested to exercise care in the disinfection of the clothing of patients suffering from infectious diseases, especially cases coming from the soldier camps, and that they be notified that the use of a disinfecting-plant is at their disposal.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

A RECENT IMPORTANT LEGAL DECISION AS TO EXPERT EVIDENCE—SOME PHASES OF MEDIEVAL MEDICAL PREJUDICE AMONG THE COMMON PEOPLE—A PROTEST AGAINST GERMAN INTERFERENCE WITH THE POSEN CZECHISH MEDICAL CONGRESS—PROFESSOR VON ROSTHORN RESIGNS AT PRAGUE—INTEREST IN ARTIFICIAL ALBUMOSES AND CLINICAL VIEWS AS TO EGG-ALBUMEN.

BERLIN, September 5, 1898.

A RECENT decision of the German Reichsgericht (court of last resort), at Leipzig, in the matter of expert medical testimony seems of special interest to medical men generally. It settles an extremely knotty question, in which doctors have usually been imposed upon while in the witness stand, and for which, so far, they have had no redress. The doctor who wins his suit had been summoned as an ordinary witness and was offered the ordinary fees for such services, which are, of course, extremely small. During the course of his examination under oath, however, he had been asked some questions that had brought out not only his knowledge of the facts of the case, but his medical opinion as to certain of these facts. He answered the questions, but refused to accept ordinary witness fees as a compensation, and sued for medical-expert fees, the amounts of which are definitely settled by German law. The defense was that he had been summoned as an ordinary witness and sworn as such, and that consequently and according to immemorial usage he was entitled only to ordinary witness fees. The lower courts, I believe, decided against him, but the Imperial Court viewed the question from a higher plane of equity than the commonplace of usage, and decided that a medical opinion given by a doctor under oath is expert evidence, and must be paid for as such, even though the doctor has been summoned and sworn as an ordinary witness.

So far it has been the custom to say that the doctor must himself guard against answering questions that included the expression of his medical opinion on the facts in such cases. But this has been manifestly unfair. It throws the burden of maintaining his rights on the witness at a moment when, perhaps, all his presence of mind is required to keep his facts from being twisted into perverse significance by an acute lawyer thoroughly accustomed to cross-examination. Besides, even after the most careful protesting as to the answering of certain direct questions expressive of medical opinion, a sharp cross-examiner is often able to so manage the recital of the

facts and their connections and relations that an inference of medico-legal value quite sufficient to be of use in influencing the jury is secured.

This new decision relieves the doctor of all further need for watchfulness in the matter. He simply answers all questions put to him to the best of his knowledge. If in the opinion of the court his answers include the expression of medical opinion, then his evidence must be paid for as expert medical evidence. Let us hope for some such thoroughly simple and satisfactory and eminently just settlement of the question in America.

Some time ago, in a small town in the Low Countries, there was reported by the newspapers a case of witchbaiting that was thoroughly traditional in its way, and showed that the old spirit is not all dead yet. Two young people in a family had died of consumption. They had reached manhood seemingly in perfect health, and then one after the other had sickened, pined away, and died. A third, a sister was spared for a year or two longer, and then she, too, began to decline. The villagers finally accused an old woman of the village who lived alone on its confines, and who was supposed to have some reason for having a grudge against the family, of having bewitched them, and being the cause of their deaths. They threatened her with all manner of dire evil unless she should raise the blighting charm she was supposed to have fastened upon her victim. Naturally threats availed nothing. Finally, she was dragged before her supposed victim by the villagers, and when she refused to comply with their request to relieve the patient was seriously maltreated. She had to be rescued from her precarious position by the authorities and placed where she could be properly protected.

An analogous story, but still more medieval in character, and strikingly illustrative of the often fearful sufferings that patients suffering from chronic skin diseases had to undergo from an ignorant populace, comes from Vienna. The victim, a middle-aged man, lies at present in the surgical wards of the General Hospital. In one of the outlying districts in the Bukowina (the Bukowina is an especially backward district of the Austrian Empire east of Hungary) the patient had contracted a chronic eczema, which gradually spread until it affected most of his body. The usual home remedies were tried for it, but were of no avail. Finally, the peasants with whom he was living grew alarmed at the persistence and universality of the disease; they began to fear that it might be contagious. They refused to have anything to do with him any longer, and he was compelled to live alone in an old ruined house. A woman brought him some black bread each day, and on this he lived.

Tired of his seclusion and hardships, one day he ventured to crawl out, but was stoned back by the peasants. Another day he crawled to a farmyard near by to get some vegetables. Fearful of being observed, he crawled into the loft of a barn, from which he was ruthlessly thrown out by the owner. Severe injuries were inflicted by this fall, and a clergyman was brought to him, who supplied him with enough money to get to Vienna. At first it was feared that amputation would be necessary, for some of the hemorrhagic exudates in bruised portions of the limbs had become purulent; it is hoped, however, now that recovery from his sad state will be complete and without mutilation, that he can be sent back to his home entirely well, eczema and all. The poor, unfortunate fellow is overjoyed at the prospect, seems to harbor no ill feelings against his persecutors, and is only anxious to be well again. He had practically given up all hope of ever again associating with his fellow-men, and considered himself hopelessly condemned to the solitary life of a leper. One would scarcely expect incidents so characteristically medieval at the end of the Nineteenth Century, but they occur as examples of what old prejudices were capable of, and some of it lurks in much higher circles than the cases given illustrate.

As the result of the German Government forbidding the attendance of foreigners at the Congress of Slavish Naturalists and Physicians at Posen, the sessions announced for this year are, as I said recently, not to be held. The Polish physicians of Cracow and Lemberg, Austrian subjects, have filed a protest with the Austrian Government in the matter. Austria and Germany are allies, and this forbidding by one State of the visit of subjects of the other for scientific purposes is a serious violation of at least the spirit of the alliance between the two countries. Owing to party differences in the Austrian Parliament the Slavs practically hold the balance of power, so that it is not probable that the protest will be allowed to drop until it has at least found its way into some diplomatic interchange of notes in the matter between the two countries.

As another feature of the strained state of affairs between the Czechs and the Germans at Prague, and the consequent unpleasantness between the two universities, with the gradual decrease in attendance at the German University of Prague, comes the announcement of the resignation of Professor Rosthorn, which took effect at the end of the present semester. It is not known whether he will go to Graz or Utrecht. This is the first resignation from the faculty of the German university because of the political difficulties, though there would seem to have been sufficient reason in certain cases before when Czechish sentiment ran so high that there was actually danger of bodily injury being inflicted. The resignation is stigmatized by German journals as an abandonment of the standard in the presence of the enemy, but it scarcely requires the eye of a prophet to foresee that under the circumstances his example must be followed sooner or later by others if the German University is maintained at Prague. The only hope of a really successful revival of the university lies in its removal into territory more German than Prague, where less than 30,000 of the 200,000 inhabitants are Germans.

In the midst of the interest manifested recently in artificial foods, of which albumen is the principal constituent, the present position of the clinicians with regard to egg-albumen, one of the purest forms of natural albumen easily available for general use is a very interesting commentary on the subject. It has changed somewhat from the traditional medical opinion on the subject, I think. I

heard a distinguished clinician, whose great forte is dietetics, remark not long ago that he would as soon advise a patient with a delicate stomach, an invalid, or a convalescent to take raw meat as to take raw eggs. The primary coagulation of the albumen so easily accomplished by means of heat calls for the expenditure of not a little vital energy. It is often not completely accomplished when digestion is weak, and so albumen passes through the digestive tract absolutely unassimilated or is assimilated in a form in which it is unavailable for tissue metabolism, and is excreted by the kidneys in a form of alimentary albuminuria. He considered, therefore, that the traditional prescription of egg-nog, the eggs merely beaten up raw in milk, for invalids is a mistake.

As to the cooking of eggs, he did not think hard-boiled eggs so difficult of digestion as usually thought. The main difficulty is the penetration into the coagulated albumen of sufficient digestive fluids. This could be readily overcome if the albumen were divided by mastication or during its preparation into sufficiently fine particles. In general the specialists in diseases of the stomach and intestines seem to be agreed that eggs are often unsuitable in disturbances of the digestive tract, though it is so usual to recommend them as a bland, unirritating article of diet. When abnormal fermentation is already going on and diarrhea is present, the nitrogenous portions of the albumen are liable to cause further trouble. When constipation exists, and absorption and evacuation is delayed, higher and lower albumoses than those available for tissue metabolism are formed, and add to the toxemia, for the dividing line between wholesome and toxic albumoses is a very narrow one.

Finally, there are some of the specialists in kidney diseases who seem to be of the opinion that just as alimentary glycosuria may lead to genuine diabetes, so alimentary albuminuria may lead to a vitiated habit of kidney epithelium that allows the passage even of a serum albumen. From this to true degeneration and actual nephritis is but a step which has so far not been clinically observed, but which the well known insidiousness of nephritides might easily have permitted to escape notice so far.

REVIEWS.

A System of Practical Medicine. By American Authors. Edited by Alfred Lee Loomis, M.D., Late Professor of Pathology and Practical Medicine in the New York University, and William Gilman Thompson, M.D., Professor of Medicine in the Cornell University Medical College, New York. Volume IV. Philadelphia and New York: Lea Brothers & Company, 1898.

This volume completes this system of medicine, auspiciously begun a year ago. Like its predecessors it bears the stamp of American teaching and research and is marked, possibly, by more originality in these respects than the preceding volumes. The subjects are judiciously arranged and overlapping of ideas is thus, to a large extent, avoided.

The volume deals with the diseases of the nervous system and mind, the vasomotor and trophic disorders, osteomalacia, rachitis, rheumatism and its allies, obesity, scurvy, and Addison's disease. Among the contributors are Drs. M. Allen Starr, F. G. Finley, Edward D. Fisher, C. A. Herter, Charles L. Dana, J. T. Eskridge, F. X. Dercum, Charles K. Mills, Wharton Sinkler, and W. Gilman Thompson (whose paper on "Seasickness" is included among functional nervous disorders). The diseases of the mind are discussed by Drs. William B. Pritchard, Willis E. Ford, William Noyes, Landon Carter Gray, Pearce Bailey, and Morton Prince. The diseases of the muscles are treated by Dr. Finley.

Dr. W. Gilman Thompson writes on rheumatism, gonorrheal arthritis, arthritis deformans, gout, lithemia, obesity, and scurvy. Dr. Finley contributes an article on osteomalacia, Dr. A. Jacobi one on rachitis, and Dr. Coleman writes on Addison's disease.

Since the views of most of these gentlemen on the various subjects assigned to them are well known, it has seemed wisest to the reviewer simply to mention the topics without discussing them. A system conceived on the lines of this one best achieves its purpose through a careful selection of authors and little editing. This system is a series of monographs by able teachers and writers on American medicine, is modern in every sense of that ill-used word, is broad and comprehensive, and represents most completely the present status of medicine in the United States. It is one of the few books of which a reviewer can honestly say that "it should be in every physician's library and in the hand of every medical student."

Handbook for the Hospital Corps of the United States Army and State Military Forces. By Charles Smart, M.D., Deputy Surgeon-General, United States Army. New York: William Wood & Co., 1898.

This short but complete treatise, comprising as it does the general management of post and field-hospitals, sanitary care of camps, the essentials of anatomy and physiology, as well as a more detailed course of instruction in special duties in emergencies of military medicine, bears the stamp of approval of the Surgeon-General of the Army. As a text-book it will materially assist those members of the corps who wish to raise their qualifications to the higher standard required of them than of the detailed men previously on duty with the Medical Department. The duties of stewards and acting-stewards, varied as they are, require thorough familiarity with military discipline and drill, nursing, first-aid, cooking, pharmacy, clerical work, field work, and the care and management of animals. These duties are, under the direction of the surgeon, to look after and distribute hospital stores and supplies, to care for the hospital property, to compound and administer medicines, to supervise the preparation and serving of food, to maintain discipline in the hospital and watch over its general police, to prepare the hospital reports and returns, to supervise the duties of the hospital corps in hospital and in the field, and to per-

form such other duties connected with their positions as may, by proper authority, be required of them. While the special instruction of the order lies in these matters, and the higher education of the studies must be directed by the surgeon, the volume under review may well supplement this practical training. Besides those mentioned, the subjects of the sanitary care of camps, construction, drainage, water-supply, and ventilation of wards, and executive duties are discussed. There are well-illustrated chapters on fractures and dislocations, asphyxiation, poisoning, hemorrhage, and insensibility, with some concluding remarks on the elements of cookery.

HAY-FEVER AND ITS SUCCESSFUL TREATMENT. By W. C. HOLLOPETER, A.M., M.D., Clinical Professor of Pediatrics in the Medico-Chirurgical College of Philadelphia; Physician to the Methodist-Episcopal Hospital. Philadelphia: P. Blakiston's Son & Co., 1898.

THE nature of the "periodic influenzas" and the rationale of their successful treatment have been the subjects of unnumbered treatises, and so-called specifics have been as numerous as the theories of causation. The short treatise under consideration embodies the suggestions of a practitioner who claims remarkable and uniform success with a simple therapeutic procedure; this consists in thorough scrubbing of the entire nasal mucous membrane with an alkalin solution (Dobell's), and the subsequent application of a mild solution of menthol in albolene. This rigidly simple form of treatment is said to have given relief to over 200 patients. Undoubtedly the author is to be congratulated upon such results, no less than upon the interesting chapters on the history of hay-fever under its multitudinous *noms de guerre*, and those on etiology and the theories of its pathogenesis. The thorough clinical study of this affection and the exhaustive review of the literature related to it, in a brief and succinct form, give us the essentials of the subject most attractively.

As much can not, unfortunately, be said for such paragraphs as the following: "Some years ago, in the dispensary, I made a somewhat prolonged study of the nasal secretion of young children waiting for treatment for various simple disorders, and it was found that, although a child might have no constitutional indication of the disease whatever, often the bacteria of diphtheria, *scarlet fever*, *measles*, *whooping-cough*, or tuberculosis were present in the nasal secretions."

Details of the "prolonged bacteriological study" by which specific micro-organisms of such importance were identified and isolated, will be impatiently awaited by pathologists, who will, undoubtedly, give a warm welcome to "bacillus scarlatinæ" (Hollopeter) and to "micrococcus putationis (Hollopeter) of measles."

ELECTRICITY IN THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE NOSE, THROAT, AND EAR. With 161 Illustrations. By W. SCHEPPEGRELL, A.M., M.D., ex-Vice-President American Laryngological, Rhinological, and Otological Society; Member American Academy of Medicine, etc. New York: G. P. Putnam's Sons, 1898.

THIS is a most complete and able presentation of the entire subject of electrotherapeutics in rhinology, laryngology, and otology by an author of acknowledged standing, whose rich personal experience is here supplemented by a thorough review of the literature. The result of this systematic management of the material is to present, not only clear and succinct theoretical considerations, but simple, though complete, practical methods which must form a valuable aid to the student or practitioner in the application of electricity in these branches of medicine, as well as a convenient and useful book of reference for the busy specialist.

Among the most valuable chapters are those on the general principles of electrophysics and electrophysiology, definition of units of measurement and modes of action, generation of current, arrangement of cells and induced currents. The subject of examination with electric light of the accessory sinuses (transillumination) is treated with special thoroughness. The scope of the work may, perhaps, be best indicated by a simple citation of a number of important subdivisions: electrocautery, electrolysis, cataphoresis, electromagnetic appliances, microphone, massage in ololaryngology, intranasal vibrators, pneumomassage of ear, and a complete study of the use of the X-rays.

AN AMERICAN TEXT-BOOK OF GENITO-URINARY DISEASES AND DISEASES OF THE SKIN. Edited by L. BOLTON BANGS, M.D., Consulting Surgeon to St. Luke's Hospital; Visiting Genito-Urinary Surgeon to St. Mark's Hospital, New York, and W. A. HARDAWAY, A.M., M.D., Professor of Diseases of the Skin and Syphilis, Missouri Medical College, St. Louis. Illustrated. Philadelphia: W. B. Saunders, 1898.

THIS volume, of ponderous size, is uniform with the other "American text-books" issued by the same publisher. There are forty-seven contributors, most of whose names are familiar as specialists in one or the other of the two departments of medicine with which the book deals. The work, as a whole, shows evidence of careful editing, and may be put down as a very excellent *résumé* of the subjects treated. Here and there a few grammatical errors assert themselves, and there is a certain unevenness which is readily accounted for by the large number of writers.

Without wishing to discriminate, we point out the excellence of the articles on "Diseases of the Male Urethra" (Dr. Lydston), "Diseases of the Prostate" (Drs. White and Wood), "Diseases of the Ureter" (Dr. Fenger), and "Hereditary Syphilis" (Dr. Jacobi). The original pathologic work of Dr. Pollitzer on the xanthomata, which he finds to contain degenerated muscle-fibers, is significant. Dr. Tuholske's discussion of the tropical skin diseases is excellently done. It is almost impossible to go further into this huge work without taking up too much space. The book represents accepted teachings, and will undoubtedly meet the kindly fate it deserves. It is splendidly illustrated with engravings and colored plates, and is well printed on good paper. We could almost wish that the publisher had issued it in two volumes.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY. Ninth session, held in Washington, D. C., May 4, 5, and 6, 1897. Edited by FLOYD M. CRANDALL, M.D. Vol. IX. Reprinted from the *Archives of Pediatrics*, 1897.

THIS number of the transactions contains so many valuable articles that but brief reference can be made to some of them here. Of special interest is a paper by Adams on the "Evolution of Pediatric Literature in the United States." There are two contributions from the pen of the late O'Dwyer, one on "Congenital Stenosis of the Larynx," and one on "Retained Intubation Tubes." Both are very timely. Koplik gives a short account of the method he uses for the rapid bacteriological diagnosis of diphtheria, a method which is certainly deserving of further trials. Jacobi describes a very rare case of sarcoma of the cutis of the newly born, with a full bibliography. Huber details a case of goiter cured by thyroid extract, and Kerley reports a cure by the same remedy in a case of exophthalmic goiter. The volume closes with a study of abscess of the brain by Holt.

INFLAMMATION OF THE BLADDER AND URINARY FEVER. By C. MANSELL MOULIN, M.D. (Oxon), F.R.C.S., Surgeon and Lecturer on Surgery at the London Hospital. Philadelphia: Blakiston, Son & Co., 1898.

THIS is a brochure based largely on clinical observations, supporting the laboratory experiences of Rovsing and Melchior that the mere introduction of pus-producing organisms into a healthy bladder does not suffice to produce cystitis. The bacillus coli communis was found to be the cause of most of the cystitis. The author is skeptical as to gonorrheal cystitis being caused sorely by the gonococcus; he regards it as a mixed infection. Mr. Moulin holds that more frequently the infection in tuberculous cystitis is by way of the lymphatics descending along the ureter and not secondary to a descending ureteritis infected from a diseased kidney. With propriety the author emphasizes the disadvantage of the Trendelenburg position when operating on old men afflicted with emphysema.

SKIN DISEASES OF CHILDREN. By GEORGE HENRY FOX, A.M., M.D., Clinical Professor of Diseases of the Skin, Columbia University, New York. New York: William Wood & Co., 1897.

THIS work is a reproduction, with some additions, of a series of articles on skin diseases that have already been published in the *American Journal of Obstetrics*. It is difficult to understand what purpose a book of this character can subserve. While there are diseases of the skin that are more common in childhood than in adult life, there are virtually none that are wholly peculiar to this age. On the other hand, the small scale on which the profuse illustrations are carried out, renders them almost useless for diagnostic purposes. The character of the text may be judged from the fact that the entire subject of lupus and the tuberculides is treated in ninety-five lines of type.

THERAPEUTIC HINTS.

For Mucous Patches.—KIRSTEIN has found a five-per-cent. solution of corrosive sublimate very efficacious for swabbing syphilitic patches of the mouth and pharynx, causing their disappearance more rapidly than any of the drugs commonly employed for the purpose.

Treatment of Enteroptosis in Children.—In order to overcome the constipation accompanying this condition, BOAS replaces the purgative or alkaline mineral waters generally prescribed, and which he has found harmful, by enemata and by drugs which tend to disinfect and stimulate the intestines. Of the following formulæ he gives preference to that containing resorcin:

1. ℞ Bismuthi salicylat. . . gr. v
   Ext. nucis vomicæ . . gr. ½–gr. i.

M. Ft. chart No. XX. Sig. One powder three times a day after eating.

2. ℞ Resorcin . . . . gr. xxx
   Ext. nucis vomicæ . . . gr. iiss
   Aq. chloroformi . . . ℥ iv
   Aq. menthæ pip.. . . . ℥ i.

M. Sig. Two teaspoonfuls three times a day after eating.

3. ℞ Bismuthi salicylat. } aa . . gr. lxxv.
   Beta-naphthol }

M. Ft. chart No. XXX. Sig. One powder three times a day after eating.

Formula for Quinin in Solution.—The prescribed dose of the following mixture is added to a wineglass of water in which five grains of bicarbonate of soda have been dissolved, and is drank during effervescence. The taste of the medicine thus given is not unpleasant, and it is well borne by the stomach:

℞ Quininæ sulphat. . . . . ℥ i
   Ac. citrici . . . . . ℥ iiss
   Syr. cort. aurantii } aa . . . gr. xv
   Syr. simplicis }
   Aq. dest. . . . q.s.ad ℥ v.

M. Sig. Ten drops to be given as directed.

Administration of Antipyrin and Salicylate of Soda.—BRICEMORET discourages the administration of these drugs in capsules, since in concentrated form they often cause gastric pain and irritation. Antipyrin may be given advantageously in a glass of Vichy or seltzer, with or without the addition of a little citric acid.

Salicylate of soda should be dissolved in at least twenty times its weight of water. Bricemoret prescribes 90 grains of the drug to a mixture of 2½ ounces, each of water and syrup of sweet orange peel, and 1 ounce of curaçoa. Each dose of this mixture is given in half a glass of effervescent water.

Ointment for Psoriasis.—

℞ Ichthyol }
   Ac. salicylici } aa . . . gr. xlv
   Ac. pyrogallici }
   Ol. olivæ } aa . . . . ℥ iiss.
   Lanolini }

M. Ft. ungt. Sig. External use.—*Richter.*

ORIGINAL ARTICLES.

ANOTHER VIEW OF CONSERVATIVE SURGERY OF THE TUBES AND OVARIES.[1]

BY HENRY C. COE, M.D.,
OF NEW YORK.

THE history of gynecological surgery in America during the past fifteen years has been marked by a series of radical changes which, to a foreign observer, must doubtless seem not a little puzzling. Three or four years have often sufficed to effect an entire transformation of the opinions and practice of our representative surgeons. The reproach that we have been carried to and fro with every wind of doctrine has not always been undeserved. You will recall how promptly we adopted the views of Lawson Tait, the operation to which his name is attached being performed hundreds of times within a few months after it was introduced into this country. Every foreign surgeon of note who has visited our shores has left his impress upon us, and has raised up a host of imitators, no matter how radical may have been his methods. From one extreme to another the pendulum has swiftly vibrated, rarely stopping in the middle of its swing. With all these changes in surgical methods this Society has been intimately associated. The hard-fought battles in which we have engaged, honest and manly, and without any tinge of bitterness, have not been in vain. A most commendable trait in our Fellows has been their readiness to correct their errors by the light of experience. A review of our *Transactions* will convince the impartial reader that, although we have kept fully abreast of modern methods, even the most radical, some of our best work has been in the line of conservative surgery. I need only to allude to the valuable papers in this line by eminent authors, some of whom will meet with us no more.

I approach this subject in a spirit far from pessimistic, feeling that, as yet, we are probably only groping after the truth. Ten or twenty years from now others will see clearly what we now see "through a glass darkly." We are all aiming at one end, and if at times we seem to hold contrary views, so much the better; the truth will sooner appear.

No man has a greater sympathy with the conservative movement in pelvic surgery than I; in fact, my position was once exceedingly unpopular. When one recalls how a few years ago at the operating-table an ovary was drawn out of the abdominal cavity, and when found to be a little larger than normal, with a few cysts on its surface, it was called "cystic," or, if it had undergone normal atrophy, was pronounced to be "cirrhotic"—and in either case was promptly removed—one feels that there is great cause for thankfulness that we have learned better. If such an ovary was adherent, so much the more reason was there for removing it, without much regard to its macroscopic appearance. The familiar diagnosis "catarrhal salpingitis" was not infrequently a sufficient excuse for extirpating a tube which was possibly the seat of ordinary menstrual congestion. Most of us must plead guilty to such errors in the past, and we rejoice that this kind of surgery has been banished, never to return.

It is my purpose to inquire briefly whether we are not in some danger of going to the other extreme. The word "conservatism" is often on our lips; in fact, we have come to use it somewhat loosely. Baldy expresses the views of not a few when he says: "I have no objection to conservatism when I know what it means." It is not necessary to review the literature of this subject, with which you are all familiar, notably the papers of our esteemed Fellows. Now that we have had further experience with the matter it is not improper to ask it the results of conservative surgery of the adnexa are all that they have been represented to be. In the early, or what may be called the statistical, stage of abdominal surgery the test of the successful operator was simply recovery from the operation. Now, it is the relief of symptoms, or the restoration of impaired functions. In other words, we look to ultimate rather than to immediate results. This is an essential difference which, in itself, marks the progress of our art; theory has given place to practice. Once the death of the patient was a proof of failure; now, the persistence of pain and other distressing symptoms, for the relief of which the operation was performed, are evidence of some error in diagnosis or technic.

I do not intend to waste the time of this intelligent audience in defining what we understand by conservative surgery of the tubes and ovaries. As I understand it, it consists essentially in the preservation of a sufficient amount of ovarian tissue to con-

[1] Read at the Twenty-third Annual Meeting of the American Gynecological Society, held at Boston, May 24, 25, and 26, 1898.

tinue the functions of menstruation and ovulation, and, at the same time, by maintaining the patency of the Fallopian tube, to render impregnation possible. The question of priority in this field, as in every other, is a matter of secondary importance. Martin admits that Spencer Wells punctured dropsical follicles as far back as 1864, while I recall that this was a common practice with Dr. T. G. Thomas many years ago. The work of Martin, Schroeder, and Pozzi abroad, and of Polk, A. P. Dudley, and many others in this country, is well known.

What, may we ask, is the true motive for conservative work in this direction? The answer may be given from the standpoint of the patient, or from that of the surgeon. A young woman naturally shrinks from the thought of losing both her ovaries. If she is unmarried, the fear that castration may lead to essential changes, physical and mental, is one which we can no longer regard as purely sentimental. The belief that profound disturbances commonly follow this operation is too deeply rooted in the minds of the laity to admit of argument. I need only refer to the last classical paper of our lamented Goodell, whose dictum in regard to the advisability of preserving the function of menstruation whenever possible has been accepted by all thoughtful men. If a woman is married, but has never borne children, the hope of future pregnancy is often so strong that she is willing to endure any amount of suffering rather than to be relieved at the cost of a sacrifice of the prospects of maternity.

For the surgeon the problem is one based upon his previous experience with the ultimate results of entire removal of the adnexa. The disturbances attending the artificial climacteric are so familiar to us that there is nó one present who does not recall cases in which he honestly believes that the patient would have been better off if he had not operated at all.

Granting that the severity of these phenomena, especially the relative frequency of insanity following castration, have undoubtedly been exaggerated, the fact still remains, as Goodell has so emphatically stated, that castration is often followed by deplorable consequences. We are glad to think that these bitter words which he wrote five years ago are no longer true: "The removal of the ovaries has developed into a busy industry, by which in city and in country, very many women have been, and are being, mutilated, both needlessly and on the slightest provocation." By preserving the function of menstruation we certainly avoid many of these unpleasant sequelæ. As regards the question of future pregnancy, the surgeon is naturally more indifferent than the patient. From his standpoint, the removal of diseased organs and the relief of distressing symptoms is the great desideratum. If pregnancy may occur later with perfect safety to the patient, so much the better. He cannot, however, avoid being strongly biased by her earnest wishes in the matter.

You are familiar with the technic of the operation in question. We all know how to puncture or to excise small cysts of the ovary, to remove portions of the gland which present macroscopic evidences of disease, to break up adhesions, to catheterize and to resect tubes, to perform "salpingopexie," as Pozzi calls it—that is, to attach the ovary or a portion of it to the stump of the resected tube. Some of us have even gone so far as to preserve portions of pus-tubes, of purulent ovaries, of dermoid cysts, or of larger cysto-adenomata, which seemed to contain normal stroma. The vital question is, in performing these operations, Are we certain that we always accomplish the results aimed at? Do we relieve pain, ward off immediate or future danger from the patient, preserve the functions of menstruation and ovulation, and cure sterility, or, at least, favor conception in a woman who would not otherwise have become pregnant except for our interference? These are difficult questions to answer; at least our data are not sufficiently numerous to justify us in answering them dogmatically. It is a mark of our fallible nature that we are prone to see what we wish to see. The enthusiastic advocate of a certain method of overcoming stenosis of the cervical canal reports a long list of cases in which conception followed his peculiar method of operation, or the insertion of a specially devised stem pessary. But how many of these patients would have become pregnant if no operation had been performed?

I need not remind you, with your wide experience, of the singular manner in which the ovaries continue to discharge their functions and conception takes place under conditions which, to the human mind, seem impossible. Who has not seen menstruation, in every respect regular, occurring in women with cancer of both ovaries, with double ovarian abscesses, with large cystomata, when the most careful search fails to disclose any macroscopic evidences of normal stroma? Who has not observed pregnancy in women with advanced carcinoma of the cervix uteri? We cannot explain these things. They only show how often Nature works successfully under the most unfavorable conditions. The idea is a fascinating one that we can deal with abnormal conditions in the pelvis just as a skilful jeweler repairs a damaged watch; that, by removing a few adhesions here, excising a little tissue there, restoring the patency of an occluded canal, we can read-

just the delicate mechanism, and, as it were, restore lost functions.

The simplest form of conservative treatment consists in separating the adhesions around tubes and ovaries which present few if any macroscopic evidences of disease. This is, undoubtedly, a most valuable procedure, since these adhesions are often the cause of abdominal pains entirely out of proportion to the local lesion. My experience is certainly not different from that of my hearers when I say that, while many of these patients have been greatly benefitted as regards the relief of both dysmenorrhea and of persistent pains, the adhesions have often reformed. It is safe to say that up to the present time no method of absolutely preventing the reformation of such adhesions has yet been discovered. They occur after the simplest aseptic celiotomies; in fact, it is the rule to meet with them in secondary operations. Although I have practised the method frequently, I have always regarded the mere separation of such adhesions by vaginal section as an operation of no permanent value, especially when the ovaries were prolapsed in Douglas' pouch. They naturally tend to resume their former position, and to become fixed by fresh adhesions. It has seemed to me much more rational to employ the abdominal route, and, after separating an adherent ovary, to suture it near the pelvic brim. Conception has undoubtedly followed this simple procedure, but one can instance quite as many cases in which the patient became pregnant with one or both ovaries buried in adhesions.

A further step in the direction of conservatism is the puncture or excision of small cysts on the surface of the ovary. This seems to carry us back to the early days, when we used to remove such ovaries simply on suspicion. Surely, we have learned a little pathology since then; among other things, the fact that such cystic ovaries are rarely the forerunners of large cysto-adenomata, and that dropsical follicles, the size of marbles, may still contain healthy ova. Pozzi has written much on the subject of igni-puncture of sclerotic ovaries. But, in spite of the amount of honest work which has been expended on the histology of the ovary, we are not yet in a position to define strictly the limits between normal and pathologic cirrhosis in the stroma. Doubtless in the hasty inspection at the operating-table corpora fibrosa are frequently mistaken for inflammatory thickening. This being the case, how do we know, when we puncture or excise a cyst, or an area of supposed cicatricial tissue in the ovary, that we are really doing the patient a service by removing a pathologic condition? That she becomes pregnant afterward is hardly a proof that the operation was a direct cause of pregnancy. Invest the procedure with high-sounding terms as we may, it still remains an experimental attempt to remove what we only suspect may be a cause of future trouble. Curettement is usually performed as a preliminary step, so that in successful cases there must always be considerable doubt as to whether this or the abdominal operation was the true factor in overcoming sterility.

It has been assumed by those who have written on this subject that the risks in ovarian and tubal resection are practically *nil*, but the writer is personally cognizant of a case in the practice of an eminent surgeon in which secondary hemorrhage followed the excision of a follicular cyst per vaginam. It was necessary to open the patient's abdomen several hours after the operation in order to check the bleeding, and her escape from death was little short of miraculous. In the case of small purulent and dermoid cysts of the ovary, excision of the diseased portions and suture of the raw surfaces is certainly not entirely free from danger, since one cannot be absolutely certain that septic foci are not left behind. Délanger, one of the enthusiastic followers of Pozzi, admits that it is practically impossible to remove all the diseased tissue, and that we can only hope to reduce it to a minimum. Pozzi's theory that the action of the cautery causes the absorption of sclerotic tissue is largely theoretical; in fact, he limits the application of this method to what he calls "microcystic degeneration, and diffuse or edematous oöphoritis." Landau calls attention to the well-known anatomic fact that atresia following gonorrheal salpingitis is really a conservative process of Nature, and asks, quite pertinently, why, then, we should open up such tubes and expose the patient to the risk of a fresh attack of perisalpingitis, or even of death from infection? It is an elementary fact that unless a bacteriologic examination is made during the progress of the operation we are not in a position to affirm with any degree of positiveness concerning the infectious character of the fluid contained within an occluded tube. Pozzi not only asserts that fatal cases of sepsis have been reported after resection of the tubes, but believes that the reason why more women do not die is presumably due to the fact that the distal ends of the tubes again become agglutinated, or else are surrounded by fresh adhesions.

In my experience, which now includes more than thirty cases (nearly all within the past three years), the immediate ill-effects of the operation have not been such as to prejudice me against it on the ground of the added risk. The question as to the subsequent condition of the patient is more important. In all the cases in which I have operated it has been for the purpose of

relieving severe pain and dysmenorrhea, and removing adnexa which were hopelessly diseased, or were the seat of small neoplasms. Most of these patients have been kept under observation, and with some of them it has been necessary to perform a secondary operation. This experience has been supplemented by secondary celiotomies performed upon patients who had previously undergone conservative operations at the hands of other surgeons. Doubtless this experience is not an uncommon one. As regards relief of symptoms, the following points have been noticed:

Relief of Pain.—In several instances in which dense adhesions were separated, the tube and ovary on one side were removed, and on the opposite side were resected and secured as nearly as possible in their normal position, the results were not as satisfactory as could be wished. The adhesions evidently reformed, the patient suffered from practically the same pain as before, and but slight difference was noted as regards dysmenorrhea. In all these cases the convalescence was afebrile, no drainage was employed, and, with few exceptions, absorbable sutures and ligatures were used. An examination of several of these patients at intervals of from three to twelve months after operation showed the presence of a painful induration at the site of the resected ovary and tube. In only one instance, thus far, has pregnancy occurred and is now progressing normally, although the patient sufferred from considerable local pain and menorrhagia for several months after the operation.

Menstruation. — The variations in menstruation noted when a portion of the ovary, including from one-fourth to two-thirds of the normal stroma, was left behind, have been many. In two instances menstruation, after returning slightly two or three times, ceased entirely. In other cases the flow was slight and irregular, but persistent; in two more profuse than before, and attended by pain several days before and during the flow. In my experience the relief of dysmenorrhea has been gradual rather than immediate.

This result is hardly surprising in view of the fact that the portion of the ovary which remains has been known to atrophy entirely, or to undergo cystic degeneration. Cases in which a secondary operation has been necessary for the removal of a cystoma, developing from the remains of the stroma, or of a tubo-ovarian cyst, have been reported by Martin and others. I showed such a specimen at a recent meeting of the Obstetrical Society. Chrobak's objection, that there is great danger of ectopic pregnancy occurring in a resected tube has, fortunately, proved to be a theoretical one so far as I am aware.

The following brief notes of cases will serve to illustrate some of the points which have been made:

Case I.—This illustrates the danger of attempting to preserve an apparently healthy ovary when the opposite one is the seat of papilloma.

The patient was a young woman, aged twenty-five years, who was engaged to be married. Her physician's attention was called to her large abdomen and rapidly declining health. On examination I found a considerable ascitic accumulation; there was a small mass at the site of the right ovary. Explorative incision; several pints of ascitic fluid evacuated. The right ovary was moderately enlarged with a few papillomatous masses on its surface. No adhesions. A few papillomata the size of millet seeds were seen on the pelvic peritoneum. The opposite ovary was carefully examined, and to all appearances was perfectly normal. In view of the patient's circumstances it was judged wiser not to remove it. She recovered, married a few months later, and remained well for a year, when she again developed ascites. A second abdominal section was performed and the papillomatous left ovary was removed. She recovered, and is well at the expiration of a year.

It may be objected that this was an improper case for conservatism; and yet, judging from the condition of the opposite ovary and tube, it seemed justifiable, under the circumstances, to spare them.

Case II.—Married woman, aged twenty-six years; separated from her husband. Suffered from constant pain and dysmenorrhea. History of recurrent attacks of pelvic peritonitis, presumably of gonorrheal origin. Uterus in normal position. Both ovaries and tubes considerably enlarged, very tender, and fixed by adhesions. The patient was desirous of marrying again, and anxious that one ovary should be saved, if possible.

Vaginal section. Adhesions easily broken down. Pyosalpinx and small ovarian cyst on the left side tied off with catgut. On the right side was a cystic ovary and a large and thickened tube, the distal end being occluded. One-half the ovary was resected, also the outer third of the tube; the tube was catheterized and the mucous membrane stitched to the peritoneum in the usual manner. Convalescence afebrile. The patient's condition after operation instead of being improved was so much aggravated that, finding local treatment, electricity, etc., of no avail, I proposed abdominal section, especially as a mass the size of an orange had developed at the site of the remaining ovary. The abdomen was opened a year after the first operation. No trace of the left ovary and tube and few adhesions. On the right side was an ovarian cyst, the size of a small orange, to the surface of which was adherent the resected tube, with its end occluded. The specimen was carefully examined, and it was found that the cyst had developed from the remains of the ovary, a small portion of the stroma being still visible. The tumor was thoroughly removed and the tube ex-

sected. Convalescence afebrile. Patient's condition after operation worse than before. She menstruated more or less regularly, using twenty-four napkins, though previously the flow had been rather scanty. A year has elapsed since the second operation. She writes me within a week that although her general health is better she has practically the same pain as before and flows more profusely than ever, so I regret exceedingly that I did not remove the uterus.

CASE III.—Conservative operation. Patient aged twenty-four years; married three years; never pregnant; anxious to have a child. Sharp anteflexion of the uterus, with stenosis. To the left of the uterus a cyst the size of a large orange. Divulsion and curettement. Broad ligament cyst on the left side removed with the ovary, which was atrophied. On the right side was a cystic ovary the size of an English walnut; small hydrosalpinx. Numerous adhesions were separated, half the ovary excised and sutured with catgut, the occluded tube opened, catheterized, and the mucous membrane stitched to the peritoneum. The ovary and tube were secured near the upper border of the right broad ligament.

Convalescence afebrile. Patient has now been under observation for six months. She has persistent pain, so that she can take but little exercise, although formerly she could ride a bicycle. Examination shows a tender mass at the site of the right ovary. Dysmenorrhea the same as before. Patient somewhat relieved by the use of ichthyol tampons and electricity, but regrets that she did not have both ovaries removed.

CASE IV.—Mrs. Q., aged thirty-five years; married eight years; never pregnant. A year before one ovary and a small fibroid were removed by the late Dr. Lusk. Patient suffered from persistent pain, dysmenorrhea, and menorrhagia. Examination showed the uterus small and in normal position. Douglas' pouch was occupied by an enlarged, tender ovary, firmly adherent.

Vaginal section. Cystic ovary was drawn down, and was supposed to have been entirely removed with the tube.

Afebrile convalesence. Patient continued to have persistent pain. Had profuse, irregular hemorrhages, which rendered her practically an invalid. She desired to have her uterus removed. It was done by abdominal section six months after the vaginal operation. Numerous pelvic adhesions were broken up. There was no trace of the left ovary or tube; the right tube had been entirely removed. At the site of the right ovary was a cyst the size of an English walnut, which had apparently developed from a small portion of the stroma which had been included in the ligature. Convalescence normal. Patient discharged, cured.

CASE V.—Illustrating the fact that menstruation does not always continue if a portion of the heathy ovary is left.

Married woman, aged thirty years; one child. Operation on account of persistent pain and dysmenorrhea; cystic tumor the size of a grape-fruit to the left of the uterus. This was found to be a simple cyst of the broad ligament, with atrophy of the ovary. Tube normal. Cyst and ovary were removed. On the right side was found a large hydrosalpinx, which was removed, and an ovary, the seat of general cystic degeneration. In order to preserve the function of menstruation, about one-third of this ovary was left, including stroma which was apparently healthy and contained normal follicles. Afebrile convalescence. Six months have elapsed since the operation. The patient has not menstruated, and has the usual climacteric disturbances following castration.

CASE VI.—Persistent menstruation following supposed removal of both ovaries and tubes.

Married woman, aged twenty-seven years; one child. Operation on account of cystic degeneration of both ovaries, with adhesions, causing constant pain and dysmenorrhea. Unrelieved by a long course of local treatment, electricity, etc.

Operation uncomplicated; convalescence afebrile; silk ligatures used.

In this case a careful attempt was made to remove all the ovarian tissue on both sides. Menstruation has persisted, at irregular intervals, for five or six years, attended by more pain than before. An induration the size of a marble can be felt at the site of the stump on the left side. Patient has not been relieved by local treatment, but refuses a second operation.

In this case it is fair to assume that a small portion of ovarian stroma was included in the ligature, around which an inflammatory exudate formed.

CASE VII.—Repeated abdominal section in the same patient.

Unmarried woman, aged twenty-four years. Original trouble probably gonorrheal. Her right tube and ovary were removed by a colleague a year before. At this time the adnexa on the left side were supposed to be normal, and were simply freed from adhesions. The patient was unrelieved, and a year later came under my care. I found a mass on the left side which was extremely tender. She suffered from dysmenorrhea and profuse menstruation. On opening the abdomen I found an enlarged, generally diseased ovary, and a thickened and occluded tube buried in adhesions. No trace of the opposite tube and ovary. Diseased organs were thoroughly removed.

Convalescence afebrile. Patient was not relieved. She continued to menstruate irregularly, losing so much blood that she became quite reduced. Curettement was performed twice, without benefit. Uterus small, and contained no granulations. There remained a small induration at the site of the left stump, which was extremely tender, so that a year later I reopened the abdomen, excised the induration, which was merely an encysted ligature, breaking up slight intestinal adhesions. I found a small, atrophied uterus, which I ought to have removed, but did not. The patient remained

absolutely unrelieved, flowing profusely nearly all the time. She would have submitted to a fourth operation for extirpation of the uterus, but, unfortunately, acute intestinal obstruction occurred from which she died unrelieved.

CASE VIII. — This patient, a young married woman, who is still under my observation, was operated upon by the late Dr. Battey seven years ago. In a personal letter he stated positively that he had removed both ovaries and tubes, which were thoroughly degenerated. It is possible that a small portion of ovarian stroma remained in one of the ligatures. At any rate the patient has menstruated regularly ever since, though the flow has been scanty. The uterus is atrophied, as well as the vagina. In spite of her regular menstrual flow, the patient has had considerable local pain since the operation, and many of the nervous phenomena attending the climacteric, which have been more marked during the past year. Although she has never had children, the condition of the uterus is such as to destroy any prospects of maternity, even if this were desired.

These are simply a few cases which illustrate the unfavorable side of this question. In these cases, as well as in several others which I might cite, the element of pain and menstrual irregularity in the mind of the patient far outweighs the advantages accruing from persistence of the function, and possible hope of future maternity. This is an important practical point, because those who have written so strongly in favor of conservative operations have laid most stress on the importance of preserving the function of ovulation with the object of favoring conception.

In my experience, the first thing which women desire is to be relieved of the pain for which they have undergone the operation. When they do not find the promised relief, the question of conception becomes of secondary importance. In the case of young women who expect to be married, or of those who have been married only two or three years, this question assumes far more importance than with those who have been married for several years, or who have already borne one or more children. Here the principal object of the operation is, it is assumed, to relieve pain and to restore health. [Just after writing these lines the truth of this statement was emphasized by a case in which I sought to preserve a portion of a diseased ovary after removing the opposite one. The family physician who was present said: "Although the patient earnestly desires to have a child, unless you can promise positively that she will be cured I take the responsibility of urging that the ovary be entirely removed, as I am sure that she would prefer it."]

I would not be understood as deprecating the practice of conservative surgery; in fact, I have consistently followed the plan in every case in which I thought portions of an organ could be saved without detriment to the patient, and have had satisfactory results. But I have merely sought to emphasize the fact that the immediate and remote results of conservative treatment are not always as brilliant as we have been led to believe.

In dealing with the question of sterility we are confronted with a problem which is by no means a purely mechanical one. In spite of the vast amount of literature on the subject, it being a favorite theme with French writers, we are still as far from understanding the occult reasons for this condition as we ever were; nor does it appear that we are yet in a position to give any more positive promises, as the result of our treatment by the abdominal route, than when we were limited to procedures for overcoming stenosis of the cervical canal. From our standpoint our chief motive in endeavoring to preserve the function of menstruation, in operations upon the pelvic organs, must still be the one insisted upon by Goodell, namely, to eliminate the mental and physical disturbances which attend the artificial climacteric in women who are still in the prime of life.

In this paper I have confined myself entirely to the subject of conservative surgery of the adnexa, believing that to discuss the question of myomectomy *versus* hysterectomy would carry me beyond the limits of this discussion. It is a fruitful subject and has been well handled in the Society time and again.

Personally, I am entirely in sympathy with every effort to preserve the uterus whenever this is possible. I am glad that we have not been entirely overwhelmed by the wave of enthusiasm which attended the visits of our distinguished French confrères, and that we are coming back to our former position, that the wholesale sacrifice of uteri is not in the direction of good surgery. But to enter into this question would be to renew an old fight. Much can be said *pro* and *con*. Doubtless we have all removed uteri which we might have saved, and, on the other hand, we have preserved organs which we were obliged to extirpate at a second operation. It is easier to criticise in the study than it is to decide correctly at the operating-table. Our esteemed Fellow, Dr. Baldy, in his usual epigrammatic style, sums up the whole matter when he says that "true conservatism is what is for the best interests of the patient."

In order to facilitate discussion the following conclusions are submitted:

1. Conservative operations on the adnexa are to be commended in properly selected cases. The surgeon should avoid, on the one hand, tampering with ovaries that are the seat of slight cystic degenera-

tion or cirrhosis, and, on the other, trying to preserve supposed normal tissue in organs which show such extensive disease that it is doubtful whether the best interests of the patient (both immediate and remote) would not be served by complete removal. In many cases it is advisable to simply separate adhesions. As there is no way of preventing their reformation, it is better to suture prolapsed tubes and ovaries at their normal level in the pelvis.

2. *Anatomical Results.*—In a certain proportion of cases resected ovaries undergo complete atrophy; in others the stromal remains may form the starting-point of cysts, requiring a second operation for their removal. A tube which has been rendered patent or resected, may again become occluded, or may form a hydrosalpinx or tubo-ovarian cyst.

3. *Symptomatic Results.*—These are often entirely satisfactory as regards the relief from pain and dysmenorrhea, the preservation of the functions of ovulation, and the occurrence of conception. Per contra, constant pain and dysmenorrhea may persist, menstruation may be absent, scanty, or excessive, and pregnancy is so far the exception that it to be regarded as an unusually fortunate sequence. In any case, we are not in a position to affirm how far conception following resection of the adnexa is directly due to this procedure, or how far to the accompanying treatment—curettement, separation of adhesions, restoration of the general health, improved sexual relations, etc. Our main object is the avoidance of the premature climacteric.

4. As regards technic, experience has shown that more successful conservative work can be done by the abdominal route, for reasons that are obvious, *i. e.*, thorough separation of adhesions, suture of raw surfaces, checking of hemorrhage, avoidance of drainage, etc. Catgut is preferable as a suture material.

5. As a corollary to the above, emphasis should be laid on the fact that, since the surgeon can never know the exact condition of the adnexa before opening the abdomen, he must not allow himself to be bound by any positive promise as to his course of procedure at the operating-table. While he should endeavor to preserve healthy organs and tissues whenever this is possible, and must necessarily be guided to a considerable extent by the expressed wishes of the patient, he must not be persuaded against his better judgment to practise conservatism at the immediate risk of her life or to court ultimate failure in order to give her the more than doubtful chance of future pregnancy.

The conscientious surgeon will not express himself too enthusiastically regarding the results of conservative operations for fear of arousing hopes which may be doomed to disappointment.

THE CORRECTION OF SPINAL DEFORMITY BY STAGES UNDER AN ANESTHETIC.[1]

BY V. P. GIBNEY, M.D.,
OF NEW YORK.

THE presentation of a paper which must necessarily be incomplete is, of course, to be deprecated. The great interest in the subject, however, prompts me to make this preliminary report in order to record my own observations in the immediate correction of the deformity after Pott's disease, and also in that of lateral curvature of the spine. A brief paper on this subject was published by the writer in the *New York Medical Journal* in March of the present year. A few of the cases have already been placed on record in that journal, but as I have had the opportunity of observing the patients since (indeed, they are still under observation), I am simply here to-day to report progress. The exact records or tracings I shall not reproduce, as I have not removed the corsets or the jackets in all instances for this tracing, and because, too, the cases themselves are incomplete. It will be my effort to disabuse your mind, as my own mind has been disabused, of certain erroneous impressions and certain dangers which have been suggested by writers, some of whom are simply critics. At the same time I have no desire to give the impression that the operation itself is entirely free from danger. The patient, for instance, may take ether poorly, too much force may be employed at the first operation, the disease itself may be located in a dangerous part of the spinal column, or the personal element of the patient may be a contra-indication; yet I am convinced that with reasonable care, such as orthopedic surgeons are in the habit of employing in their work, the deformity may be corrected by repeating the procedure, say half a dozen times. Again, a certain amount of correction may be secured without the use of an anesthetic by frequent renewal of the plaster of Paris or whatever dressing may be employed. Especially is this desirable when one is not thoroughly conversant with the use of plaster of Paris. Even in the best of hands excoriations may sometimes occur, and excoriations occurring in cases like these under consideration necessarily bring discredit upon the treatment. We somehow feel that we are able to maintain a good position when once secured.

In England, where plaster has for a long time been tabooed, steel and iron appliances are employed, yet such appliances are generally managed or controlled by skilful men. On the Continent plaster of Paris, with an immense amount of cotton batting, is wrapped about the body, and it does

[1] Read before the American Orthopedic Association, Boston, May, 1898.

seem to me that the deformity is bound to recur where so much cotton is employed. The ideal dressing would, of course, be a skin-fitting plaster-of-Paris bandage secured accurately about the salient points, thus ensuring a perfect fit. In this country most of us are reasonably familiar with the use of plaster, and we take certain precautions that will guard against excoriation. It may be just as well to state that excoriations are not the worst things a patient can have. Even if a small ulcer is produced over the tip of the bosse, or a long one at the side of it, there is no real harm done. The only trouble is we are obliged to discontinue the fixation, during which period the deformity will recur. In my own cases I have not seen fit to include the head in the dressing. I have employed piano felting on either side of the bosse, over the iliac crests, along the free ribs where these protrude, and have bound these on with a cheese-cloth bandage after having secured these pads more firmly by means of a needle and thread. With such precautions I rarely ever find an excoriation, and want to put this on record, although I am unprepared, as above mentioned, to give final results so far as deformity goes.

In reapplying plaster when an anesthetic is not employed, I have been in the habit recently of hyperextending the column and the hips, thus securing a very decided recession of the deformity. At the time I began this work I was under the impression that the method had not been employed in the City of New York. I find since, however, that while this is true, it had been employed in Chicago. The cases are as follows:

CASE I.—A boy, twelve years of age, in very good general condition, but with a very awkward gait, presented deformity in the dorsolumbar region, resulting from old Pott's disease, many years having elapsed since acute symptoms prevailed. The tracing was taken before force was employed, and a very thorough examination was made in the iliac fossæ, in search of psoas abscess, with negative results. It was difficult, however, to completely extend the thighs. Under an anesthetic (gas and ether) I operated March 1, 1898, by making firm pressure over the bosse. I succeeded in breaking down the deformity, so that the tracing showed a straight line. There was an immense amount of crackling, the result of breaking up of heavy and ligamentous adhesions. On removing the pressure, however, there was a little recurrence, but on applying the jacket I felt quite sure that the good position would be maintained. Following instructions of Calot and others, I put the patient to bed, intending to keep him there for the next two or three weeks. The next morning he was ready to sit up, in fact, felt no pain whatever, and, strange to say, had passed a very good night without a narcotic. After three or four days he was allowed to get up, there being no apparent reason for longer bed treatment. At the end of a fortnight we removed the jacket in order to reapply, without an anesthetic, and found a good-sized psoas abscess in the right iliac fossa. A large needle was inserted, but it was a dry tap. I applied plaster of Paris again, and a week or two later, under an anesthetic, employed more force, and have maintained this good position ever since. The abscess has given no trouble, and I doubt very much if it will. If it does I am prepared to take care of this complication.

CASE II.—A male, five years of age, deformity, Pott's disease, mid-dorsal. This boy has been in the hospital for a long time, had worn solid plaster-of-Paris jackets, and was quite accustomed to them. Examination made February 17, 1898, showed that his urine was normal; there was no pain or tenderness on pressure, and no sign of abscess. The disease was not at all active. On March 8th, under gas and ether, manual force was employed over the bosse, when the characteristic crackling was both felt and heard. While making pressure his respiration became affected a little, and the anesthetic was discontinued for one or two minutes; then, as danger seemed to have passed, it was renewed. The deformity in this case was not completely overcome. I should say it was reduced about two-thirds. He was put up in plaster of Paris, with the back in marked hyperextension. No unpleasant results followed. He was kept in bed for about two weeks; then on April 20, 1898, the jacket was cut down. There were no excoriations, except in one or two places, on the side of his body, where he had dropped some buttons. He was put in a swing at this time, and an attempt made to correct, with a fair amount of success. It has been rather difficult to keep his shoulders well back, although the plaster extended over them, and at the present writing I doubt very much whether the good position maintained at the time of the first operation remains. We expect to send him to the country for the summer, and in the fall the efforts at correction will be renewed.

CASE III.—A male, ten years of age, from the country, was admitted on April 5, 1898. There was incomplete paralysis of the lower extremities, but on the right side it was nearly complete. The reflexes were exaggerated, while there was no impairment of sensation. The deformity had existed, so far as the history was obtained, about two months only; the loss of power two or three weeks. The bosse was located in the upper dorsal. Two days after admission he was put under ether, and an attempt made to reduce the deformity, but it was only about one-half reduced. The plaster was carried well up around the neck and over the shoulders, and the dorsolumbar spine was put up in hyperextension. The following day there was a decided improvement in his limbs. He was able to move them about in bed quite freely, and he seemed anxious to stand up. This was not permitted, however, and special care was taken to prevent his sitting up. On the third day he had high temperature, and next morning it was found that he had developed scarlet fever.

He was taken at once to the Willard Parker Hospital, where he died within forty-eight hours. No autopsy was allowed.

CASE IV.—A girl, ten years of age, presented a deformity in the mid-dorsal region, the result of Pott's disease of long standing. There had been no acute symptoms for at least two years. On May 3, 1898, the spine was forcibly stretched and a plaster-of-Paris jacket applied. This child was rather nervous, and it was said that she had had for a long time, at irregular intervals, peculiar symptoms, such as spasm and pain, without any special cause. These attacks were thought to be hysterical, and left as suddenly as they had come on, never being followed by any other symptom. She was not allowed to get out of bed for three or four weeks. At this time the plaster of Paris was removed, further correction was made without an anesthetic, and this treatment will be continued until we secure a complete recession of the deformity.

CASE V.—A boy, six years of age, who gave a history of rickets. Deformity appeared some three years prior to this time, and he appeared at the Out-Patient Department of the hospital a year later. The deformity at that time was thought to be rachitic. On further examination at the time of his admission to the hospital, April 15, 1898, the deformity could not be corrected by manual force, and there was a history of pains pointing toward the disease being tubercular. He was put under an anesthetic April 20th, and direct pressure made over the bosse. The deformity was reduced at least one-half. Since then, without an anesthetic, it has been reduced still more, and he is at present under protective treatment.

These include all the cases of Pott's disease, while the following are cases of lateral curvature, in which, I am free to confess, results are far from brilliant. I am satisfied with the treatment thus far, yet it is a very slow process. One gains very little at each operation, and consequently gets discouraged. Inasmuch as the cases subjected to this procedure are extreme, as a rule, and inasmuch as the apparatus and exercises fail to effect any decidedly good results, I feel that it is our duty to resort to almost any method which is attended by the minimum amount of danger.

CASE VI.—The patient, an Italian girl, fourteen years of age, presented, at the time of her admission to the hospital in December, 1897, a very marked rotary lateral curvature in the dorsal region. This deformity had stunted her growth, and given her a typical hunchback, and it was undoubtedly as our English brethren say, "osseous." That is to say, we could affect no improvement by suspension. January 4, 1898, I attempted to stretch the back in an apparatus specially constructed for the purpose, employing one of the Schleich mixtures for anesthesia. The patient got too much chloroform and we had to desist. I question very much whether any reduction of the deformity was gained at this time. In March I made two or three attempts under an anesthetic, and secured from two to three inches increase in height. I have been careful to maintain this improvement by renewing the jackets frequently while she was suspended in the swing. Certainly at this time there is some flexibility in the column, and I am encouraged to proceed with the treatment.

CASE VII.—A girl, six years of age, who presented a right rotary lateral curvature, rather rigid and unyielding. On March 22, 1898, the spine was forcibly stretched, and a fair amount of untwisting obtained. On March 24th she was again put under an anesthetic, and once or twice since then the plaster has been renewed. She has, since then, been wearing a solid plaster-of-Paris jacket, has not been suffering from excoriations, and there is a decided gain in height.

CASE VIII.—A girl, nine years of age, S curvature, rachitic in origin. She had been under treatment for a number of years at the hospital without material change. On March 21, 1898, under ether, I succeeded in reducing the deformity about one-half. She is wearing plaster of Paris now. The plaster has been renewed once or twice, and the treatment will be continued.

Such is my experience, and I intend to renew the work with vigor during the coming fall and winter. There has been a certain number of bad results in reported cases from the other side of the water, but none, I believe, on this side. It is well to bear in mind that any good thing can be abused. At the same time we should remember that the deformities which are now under discussion are most obstinate, and at times unyielding. The aim should be to break up these osseous adhesions and to render the column flexible. This being accomplished, and care being taken to hold the spine in better position for a few months, this treatment can be followed by gymnastic methods with greater hope of success.

FACTS REGARDING THE DEATH-RATE OF DIPHTHERIA WHEN BASED ON THE MORTALITY STATISTICS OF A CITY.

BY ALBERT WOLDERT, M.D.,
OF PHILADELPHIA;
ASSISTANT PHYSICIAN TO THE OUT-PATIENT DEPARTMENT OF HOWARD HOSPITAL; PHYSICIAN TO THE OUT-PATIENT DEPARTMENT FOR DISEASES OF CHILDREN, ST. JOSEPH'S HOSPITAL.

To arrive at the truth in regard to the value of antitoxin as a curative agent in diphtheria when based on the mortality statistics of a city certain factors must be carefully considered: (1) One should be unbiased in his opinion regarding the value of a given remedy. (2) One should consider the factor that in all diseases there are certain years in which the effects seem to be more virulent than

in others, so that a series of years must be considered and compared. (3) In making the comparison one should go back to the time when bacteriologic methods were not used as a means of diagnosis. (4) A series of years must be compared both before and after the date of the introduction of antitoxin. (5) Errors in figures must be carefully noted.

Each week we read the mortality statistics of the larger cities, and often we are surprised to find that the death-rate of diphtheria, scarlet fever, and other infectious diseases appears exceedingly high, while at other times it seems relatively low. When it is low in diphtheria we judge that antitoxin is being more extensively used, and when it is high we wonder why it is so. Again, in studying the mortality statistics of hospitals we find this same condition existing, and although in some hospitals it is claimed that the antitoxin is being used and that the death-rate is not diminished over that of pre-antitoxin days, and we wonder why this is so.

The study of statistics is such dry reading that as a rule they receive but little attention. Generally we note the gross results, such as the average mortality, but when it comes to the "laryngeal cases," the "patients under one year old," the "patients requiring intubation," the "moribund patients" we begin to wander in a maze of a confusion of ideas and frequently these details are skipped. And yet these latter cases are very important. For instance, if we say that in pre-antitoxin days the death-rate of diphtheria was 29.62 per cent. (which it was in Philadelphia from 1892 to 1895 inclusive), and compare this result with that obtained in the treatment of "laryngeal cases," in "children under one year old," in "neglected or moribund cases" in which antitoxin is used, we may find that the death-rate from diphtheria in pre-antitoxin days was lower than that period in which this specific treatment was used.

Another fatal error is in comparing the death-rate occurring in years in which the mortality of nearly all diseases is low with those years in which the mortality of all infectious diseases seems relatively high. This is a great and favorite fallacy.

For instance, if we wish to prove the value of a certain remedy in the treatment of scarlet fever in Philadelphia for the year 1896, with that of 1894, it is found that in the year 1896 the death-rate from scarlet fever was 5.85 per cent. while in 1894 it was 13.63 per cent. Clearly there is yet no specific treatment for scarlet fever, yet in 1896 we find the death-rate less than half of what it was in 1894, the reason being that in 1896 nearly all diseases were milder in character than they were in 1894. As a proof of this assertion reference may be made to the official report of the Bureau of Health:

POPULATION OF PHILADELPHIA.

1892.	1893.	1894.	1895.	1896.	1897.
1,092,168	1,115,562	1,139,457	1,163,864	1,188,793	1,214,256

Death-rate of Philadelphia from all diseases from 1892 to 1897:

1892.	1893.	1894.	1895.	1896.	1897.
22.25	21.20	19.19	20.24	20.17	18.72

Number of cases of diphtheria, membranous croup, scarlet fever, and smallpox from 1892 to 1897:

	1892.	1893.	1894.	1895.	1896.	1897.
Diphtheria.....	5051	3149	3159	3351	3191	5031
Membranous Croup	not obtainable	322	449	502	404	374
Scarlet Fever.....	6350	2849	1122	1195	1042	3553
Typhoid Fever....	2304	2519	2357	2748	2489	2994
Smallpox	7	43	136	319	none	none

Number of deaths from diphtheria, membranous croup, scarlet fever, typhoid fever, and smallpox from 1892 to 1897:

	1892.	1893.	1894.	1895.	1896.	1897.
Diphtheria.....	1435	916	1047	1020	862	1231
Membranous Croup	Reported as diphtheria	243	349	329	293	243
Scarlet Fever.....	485	267	153	79	61	282
Typhoid Fever....	440	456	370	469	402	401
Smallpox.....	none	5	13	45	none	none

Mortality from diphtheria, membranous croup, scarlet fever, typhoid fever, and smallpox from 1892 to 1897:

	1892.	1893.	1894.	1895.	1896.	1897.
Diphtheria.....	25.57	29.08	33.11	30.75	27.01	24.48
Membranous Croup	Unattainable	75.46	71.71	65.53	72.52	64.97
Scarlet Fever.....	7.63	9.37	13.63	6.61	5.85	7.93
Typhoid Fever....	19.09	17.75	15.69	17.06	16.15	13.39
Smallpox.....	none	11.62	9.56	14.10	none	none

It will be observed that the death-rate of Philadelphia is gradually being reduced, and it may be added that the number of deaths from at least two common diseases has shown an improvement as shown by the following statistics:

Deaths from phthisis from 1892 to 1897; also, the death-rate per 1000 persons living:

	Deaths.	Population.	Deaths per 1000 persons living.
1892....	2709	1,092,168	2.480
1893....	2671	1,115,562	2.394
1894....	2513	1,139,457	2.205
1895....	2449	1,163,864	2.104
1896....	2514	1,188,793	2.115
1897....	2388	1,214,256	1.966

(These figures seem to refute the statements frequently made that death from phthisis is becoming more common in cities.)

Deaths from diphtheria from 1892 to 1897; also, the death-rate per 1000 persons living:

	Deaths.	Population.	Deaths per 1000 persons living.
1892....	1435	See above	1.322
1893....	916	" "	.821
1894....	1047	" "	.902
1895....	1020	" "	.876
1896....	862	" "	.771
1897....	1231	" "	1.013

In making comparisons of the mortality of diphtheria at the present time when the culture method is in vogue with that of pre-antitoxin days, we must allow for mistakes which formerly resulted when the clinical diagnosis was mainly relied upon. It might, therefore, be of interest to compare the results of the two methods of diagnosis as obtained in Philadelphia. In the report of the Bacteriologic Division of the Bureau of Health for 1895, pages 232–233, we find the following statistics on this subject based on 1207 cases:

Table A, showing the results of all cases and the relation of same to the clinical diagnosis, 1207 cases.

Diphtheria bacilli present.	No diphtheria bacilli present.	Unsatisfactory.	Clinical Diagnosis Given.		Clinical Diagnosis of Diphtheria.		Clinical Diagnosis not Diphtheria.		No Clinical Diagnosis and doubtful, per cent.
			Cases.	Verified, per cent.	Cases.	Verified.	Cases.	Verified, per cent.	
775	291	141	705	86.4	557	90.2	148	72.9	41.5

It will, therefore, be observed that the percentage of correct diagnoses made by clinical methods in Philadelphia, and subsequently confirmed by a bacteriological examination, is relatively high, being verified in 90.2 per cent. of the cases, but shows a loss when the disease was not properly diagnosed.

The culture method as a means of diagnosis was instituted in Philadelphia on May 20, 1895. Membranous croup is gradually disappearing while the percentage of cases of diphtheria shows an increase. Many argue that since the culture method has been in vogue that cases are now recognized as diphtheria, which were formerly not suspected on account of their mild character, and that a relatively large percentage of these patients would recover even though antitoxin was not used. Undoubtedly this is partly true but it evidently does not hold good for the year of 1896. It might be of interest, therefore, to give this increased percentage of cases as reported to the Bureau of Health.

Number of cases of diphtheria from 1892 to 1897, with the rate per 1000 persons living:

	Cases.	Population.	Cases reported per 1000 persons living.
1892....	5051	1,092,168	4.597
1893....	3149	1,115,562	2.822
1894....	3159	1,139,457	2.772
1895....	3351	1,163,864	2.878
1896....	3191	1,188,793	2.684
1897....	5031	1,214,256	4.143

The writer endeavored to determine approximately the number of practitioners who availed themselves of the opportunity of having a bacteriological examination made as a means of diagnosis in suspected cases of diphtheria. It is stated in the "Annual Report of the Bureau of Health" that since January, 1897, the routine work of the laboratory has consisted in the bacteriologic examination of cultures from cases of diphtheria and suspicious inflammations of the throat and nose. For the year 1897 there were 3353 persons suspected of having diphtheria, and of these 2020 proved by bacteriological examination to have diphtheria bacilli, 1138 did not have diphtheria bacilli, and in 195 cases it was impossible to make a positive diagnosis. As there were reported to the Bureau of Health for 1897 a total of 5031 cases of diphtheria, it will be observed that about 66 per cent. of the profession availed themselves of this method of diagnosis at the hands of the Bureau of Health. It should likewise be noted that of the 3351 cases in which a bacteriological examination was made 33 per cent. of them did not show the presence of diphtheria bacilli, and these doubtless would have formerly been reported as cases of diphtheria and treated as such. Doubtless if we should take a series of years we might find that the percentage of mistakes that formerly occurred from a clinical diagnosis would not be far from that increased rate of reported cases as now observed when dependent upon the culture method as a means of diagnosis.

In the American Pediatric Society's "Report on the Collective Investigation of the Antitoxin Treatment of Diphtheria in Private Practice" (MEDICAL NEWS, May 15, 1897), it was stated that the mortality in 1704 laryngeal cases (worst type of the disease) in which antitoxin was used was 21.12 per cent., and in the 668 patients operated upon the mortality was 27.24 per cent. In nearly 6000 cases in which the antitoxin was used the first day the mortality was 4.9 per cent., for the second day 7.4 per cent., for the third day 8.8 per cent., for the fourth day 20.7 per cent., and for the fifth day 35.3 per cent. A careful study of the mortality statistics of Philadelphia evidently shows one of three things: (1) The period is yet too early to base an absolute conclusion regarding the beneficial effects of antitoxin in diphtheria. (2) That antitoxin is not used as frequently as it should be; or (3) its administration is postponed to a period in the disease when the chances of recovery on the part of the patient has become gradually lessened.

Professor Koch in Rome.—It is reported that Professor Koch has already arrived in Rome for the purpose of making a searching investigation into the etiology and nature of malaria, and the methods of infection. With that object in view every facility has been placed at his disposal by the municipal and collegiate authorities.

SEPTIC BRONCHOPNEUMONIA.

BY ALBERT ABRAMS, M.D.,
OF SAN FRANCISCO;
PROFESSOR OF PATHOLOGY IN THE COOPER MEDICAL COLLEGE.

IN the conventional nomenclature of pulmonary diseases, a tuberculous and a simple bronchopneumonia are recognized. In both affections the essential anatomic condition is an accumulation of inflammatory products in the smaller bronchi and their alveolar continuations, environed by hepatized tissues. The clinical differentiation between the two forms is in the presence of tubercle bacilli in the sputum. In the adult, bronchopneumonia is capable of further division from the standpoint of the clinician. During the past ten years, I have kept careful notes of all cases of bronchopneumonia, 61 in number, which have come under my observation. In accordance with my observations I am justified in adding to the list two other forms of the disease, and have denominated them, (1) non-febrile, chronic bronchopneumonia; and (2) septic bronchopneumonia. The cases which came under observation may be divided into tuberculous bronchopneumonia, 25 cases; simple bronchopneumonia (the conventional form), 10 cases; non-febrile, chronic bronchopneumonia, 15 cases; and septic bronchopneumonia, 11 cases. The last two forms are the subject of consideration in this contribution.

Excluding the tuberculous form from discussion, it is customary to regard bronchopneumonia occurring in adults as a foudroyant affection, attended by pronounced dyspnea, cyanosis, elevation of temperature, and symptoms of collapse. In the non-febrile form of bronchopneumonia, 15 of my cases admit of analysis as follows: course, subacute in 4, and chronic in 11 cases; no elevation of temperature in any one of the cases; slight dyspnea in 5 cases. Expectoration in nearly all the cases showed the presence of staphylococci and streptococci. The physical signs were those of bronchitis confined to the smaller tubes, percussion-note dull over discrete lung areas, notably the right lower lobe and the apices, with bronchovesicular, rarely bronchial respiration.

In the septic form of bronchopneumonia (11 cases) the clinical picture was essentially that of pulmonary tuberculosis, minus the presence of tubercle bacilli in the sputum. Such cases in the prebacillary period of medicine would have been regarded as indubitable cases of phthisis; in fact eight of the patients came to me with that diagnosis. The symptoms of these cases were invariably those of sepsis—remittent and intermittent types of temperature, night-sweats, chills, pronounced and rapid emaciation, anorexia, etc. In the majority of the patients the site of disturbance was limited to the pulmonary apices. The sputum of these patients was of a purulent character and contained in most instances streptococci and staphylococci, coli communis, and pneumococci in large numbers. The prognosis in both forms just described was good, cure being secured in the majority of cases by the pneumatic cabinet. The same results might have been attained with compressed air by means of any other efficient apparatus. I lay stress upon the employment of compressed air, and advisedly, because nearly all the patients who underwent treatment had resisted the conventional therapeutic methods. I mention the pneumatic cabinet particularly, because I believe it embodies the most rational means yet devised for the administration of compressed air. The effect of compressed air in these cases virtually secured a mechanical dislodgment of the inflammatory and septic products in the smaller bronchi and their alveolar continuations. Free drainage of the septic districts is obtained by aerial lavage. If this mechanical treatment is procrastinated there is great danger of the exudate in the non-febrile forms becoming septic, and of the septic form becoming tuberculous.

In addition to this treatment, iodid of potash was employed, this drug being one of the most efficient expectorants we possess. Its liquefactive action on the exudate is almost marvelous.

The following conclusions may be formulated:

1. Bronchopneumonia may exist as a chronic non-febrile affection.

2. Septic bronchopneumonia may simulate pulmonary tuberculosis.

3. The only clinical distinction between septic bronchopneumonia and septic pulmonary tuberculosis is in the presence of the tubercle bacilli in the latter affection.

4. The specific treatment of septic bronchopneumonia consists in free drainage by aerial lavage of the septic districts by compressed air and the employment of iodid of potash to facilitate expectoration.

CLINICAL MEMORANDA.

CARCINOMATOUS THROMBOSIS OF THE BRACHIAL ARTERY.

BY F. R. FRAZIER, M.D.,
OF YORKVILLE, ILL.

MRS. J., ninety-four years of age, was first seen September 24, 1897, at which time she presented an indurated mass, about the size of a hickory-nut, located on the margin of the lower lip to the left of the median line. A diagnosis of carcinoma was made, and an operation deemed inadvisable on account of the patients' advanced age, her

feeble condition, and extensive glandular involvement. She was next seen on March 2, 1898. The lower lip was nearly destroyed. There was very extensive cervical and mediastinal glandular involvement. A suppurating fistula existed on both sides of the larynx. Two days previously the patient had experienced sudden and acute pain in the right arm. The hand and forearm were noticed to become extremely pale and cold. When seen, the hand and forearm were discolored, cold, and anesthetic, while the fingers showed a very marked tendency to dry gangrene. Her condition was bad. She was semicomatose, and had Cheyne-Stokes' respiration. A dry antiseptic dressing was applied. She died eight days later without any evidence of sepsis. Dry gangrene of the hand and forearm was present. No autopsy was permitted.

CYST OF THE THYRO-HYOID BURSA.

BY CHARLES L. SCUDDER. M.D.,
OF BOSTON, MASS.;
SURGEON TO THE MASSACHUSETTS GENERAL HOSPITAL, OUT-PATIENT DEPARTMENT; ASSISTANT IN CLINICAL AND OPERATIVE SURGERY, HARVARD MEDICAL SCHOOL.

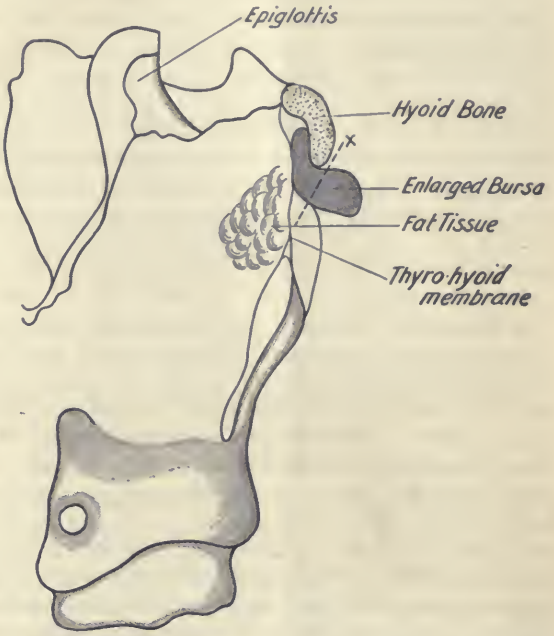
MISS B., nineteen years old, had had for about ten years a small swelling in the median line of the neck which had occasionally discharged through a pin-hole opening, a glairy mucus-like fluid. This swelling has varied in size from a pea to a hickory-nut. At times it has grown smaller from no apparent cause. Whenever the patient has had a cold this swelling has always become tense and full.

Examination revealed at the angle of the neck with the chin, just above the level of the top of the thyroid cartilage, exactly in the median line. a tumor, which was firm, elastic, rounded, the size of a hickory-nut. This tumor was attached to the deeper parts and moved with deglutition. The overlying skin was adherent in one spot where a small fistulous opening existed, admitting a fine surgical needle.

Three operations were performed upon this small tumor. The first was done in November, 1893, under cocain anesthesia. The tumor was exposed by a small transverse incision and the sac of the tumor was opened. The glairy mucus contents were evacuated. A fine probe passed downward and upward behind the body of the hyoid bone. The sac was removed down to the level of the hyoid bone and beyond this point was stimulated by the application of strong carbolic acid. The application of carbolic acid was made with the hope that the remainder of the sac might granulate and heal. The wound was closed and healed promptly. The tumor did not reappear for about six weeks but then became very evident.

On May 29, 1894, a second operation was done, again under cocain anesthesia. At this time the part behind the hyoid, inaccessible to the knife without dividing the hyoid body, was most thoroughly cauterized. The tumor again reappeared after a few weeks.

A third operation was performed on October 30, 1895, under ether anesthesia. A transverse incision was made over the swelling and the newly formed cyst sac isolated down to the body of the hyoid. There was no trace of the sac's running up behind the hyoid. This had been completely obliterated. The parts about the base of the little sac were carefully examined and no opening could be found. The wound was sutured securely without drainage by deep and superficial sutures.



Case of thyro-hyoid cyst. (In this illustration the right half of the hyoid bone and thyroid cartilage have been removed.) The bursa was excised at the point indicated by the dotted line.

Up to the present time there has been no return of the swelling. The accompanying diagram shows very well the relations of the parts involved in the cyst surroundings. Had the last operation not been successful I intended splitting the body of the hyoid bone, retracting the two halves and dissecting out the sac of the bursa, thus preventing any possible recurrence.

MEDICAL PROGRESS.

The Measurement of Sunshine at Health-Resorts.—JONES (*Lancet*, July 30, 1898) has been measuring the actinic value of the sunshine, in summer and winter, in London and at Llangammarch Wells, a mountain-resort in Wales, where the air is particularly pure and clear. He found that the actinic value of the sunshine in the latter place was in an hour of a summer's day from three to five times that of London under similar conditions of clear or clouded skies. In the winter the difference was not so marked, but the Wales sunlight was about twice as strong as that of London. A comparison with the results of similar tests made in the high Alps shows that the air may be just as pure in a mountainous district or far less lofty elevation. These tests are essentially a test of the purity of the air, as the amount of heat in the sun's rays has no effect upon the result. The method employed is briefly as follows: A solution of potassium iodid is prepared

containing 20 grams to the liter of water; also, a solution of pure sulphuric acid, 11.6 grams to the liter of water; and a third solution in which a liter of water contains 0.39 grams of powdered arsenious acid and 1.5 grams of potassium bicarbonate. To make a test of the sunlight 10 c.c. of solution No. 1, and an equal amount of No. 2, are placed together in a glass-stoppered bottle on a white porcelain plate, and exposed to the action of the sunlight. At the end of an hour the bottle is removed and enough bicarbonate of soda is added to it to just neutralize the acid. The bottle is then placed under a burette containing the solution of arsenious acid, and the latter is run in until the color of the iodin is completely discharged. The results are expressed in milligrams of iodin liberated per 1000 c.c. of solution used. Since in practice 200 c.c. of the mixed solution are used, the results obtained were multiplied by five to bring them up to the accepted standard.

Sunlight has a well-known inhibitory effect upon the life of pathogenic organisms. Direct sunlight will kill tubercle bacilli in a few hours or perhaps in a few minutes; whereas they will live for days if exposed to a very strong diffused daylight. The exhilarating effect of a burst of sunshine in the spring is probably not due to mere luminosity, but to an increased actinic action, a chemical action which we cannot very well explain, but which every one feels. In estimating therefore the value of a health-resort, the amount of this actinic value in the sunshine ought to be taken into account, no less than the number of days upon which the sun shines during the month or the year.

The Diagnosis of Frontal Empyema.—GOULY (*Med. Moderne*, May 7, 1898) says that empyema of the frontal sinuses is frequently overlooked. In typical cases three cardinal symptoms exist: violent pains at the root of the nose; nasal obstruction, and a discharge of pus from the nose or through the nasopharynx. The pain may be dull and continuous; or it may be paroxysmal with its seat in the region of the frontal sinus, or disseminated over the whole head. At times it is extremely violent, especially if the secretions can not escape from the frontal openings. The pain may be intermittent. It can be aroused by percussion on the base of the forehead.

At a more advanced stage of the affection, the skin overlying this region becomes infiltrated and edematous or there may be a hyperostosis of the external table of bone. The orbit itself is affected, and edema of its upper portion and a deviation of the globe of the eye may be noticed. Rhinoscopy will show that the openings into the frontal sinus are closed, usually by mucous polyps. The character of the pus is significant. In suppuration of the maxillary sinus the pus is almost always grumous and forms a caseous mass which does not readily flow away. In suppuration in the frontal sinus it is thick, creamy, and not fetid.

Lighting the sinus by electricity will corroborate the results of direct examination, but is not of itself sufficiently conclusive to make a diagnosis positive, especially if its results are opposed to those of other methods of examination. Both sides should be lighted and compared, in order that any difference may be manifest. Both sides are rarely affected simultaneously, as that presupposes that rhinitis and obstruction have been bilateral, which is not usually the case.

A Cancerous Family.—POWER (*Brit. Med. Jour.*, July 16, 1898) gives what is perhaps the most remarkable family predisposition to cancer ever recorded of the members of any family. A patient in the Infirmary at Peterborough had his right breast removed for scirrhous cancer in 1896. The following year malignant glands were removed from the axilla. He returned to the hospital this year with a recurrence in the axilla, too extensive to allow of removal. His father died at the age of 46 years of cancer of the breast. His mother died at the age of 86 years of no particular disease. He had two brothers and eight sisters. His first brother died at the age of 65 years of cancer of the throat. His second brother died at the age of 24 years of cancer of the left axilla, the breast never apparently having been affected. Of his eight sisters, the first four died of cancer of the breast, at the respective ages of 63, 46, 40, and 54 years; the second and third sisters having the disease on both sides. The fifth and sixth sisters were alive at the time of the report, but both of them were suffering from cancer of the breast. The seventh sister died while yet a child, and the eighth sister died in childbed.

THERAPEUTIC NOTES.

Aspiration of the Contents of the Stomach During Artificial Respiration. — BROSCH (*Therap. Monatshefte*, July, 1898) was led by an unfortunate death during the performance of artificial respiration to make an investigation of the possibility of the aspiration of material from the stomach under these circumstances. He found by thirty-one experiments made upon the cadaver that there is a strong aspirating power when artificial respiration is performed. This force is equal to the aspiration of from 1000 to 1210 centimeters of fluid (more than two pints). The latter is the maximum amount, the aspiration of which he was able to accomplish. It follows that it is impossible to remove fluids and foreign bodies from the middle and lower portions of the lungs, excepting, of course, by operative measures. The conditions for the aspiration of a large quantity of fluid during artificial respiration are more favorable in the living than they are in the cadaver. Pressure below the diaphragm is an especially dangerous procedure, as it was shown that such pressure can easily force fluids from a full stomach into the throat, the cardiac orifice, even in the living, affording little protection against such a regurgitation.

How may such a regurgitation and aspiration be guarded against? Of all the measures proposed and tested only one was found to have an absolute value, and that was the introduction of a tube into the esophagus before the movements of artificial respiration were begun. The procedure is simple enough, and it did not once fail of its end. The author, therefore, recommends that it be performed in all cases before artificial respiration is begun.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, SEPTEMBER 24, 1898.

THE ARMY INVESTIGATION.

THE determination of President McKinley to appoint a committee and order an investigation of the alleged neglect, incompetency, and abuses in the management of army affairs gave foundation for the hope that the facts concerning the War Department's conduct of the war would be brought clearly before the public and the responsibility for mistakes and incompetency definitely fixed. It would seem that the President entered upon this undertaking with all sincerity, but evidently without due consideration. The President can order an investigation and appoint a committee, but, unfortunately, no committee thus appointed can be adequately empowered, except by act of Congress, to prosecute an investigation efficiently. It cannot judicially administer an oath, compel the production of papers, or the attendance of witnesses, nor has it the power to punish indifference to its behests. In each House of Congress, however, inheres the power to conduct adequately such investigations as the present contingency requires, according to the Revised Statutes:

101. The President of the Senate, the Speaker of the House of Representatives, or a chairman of a Committee of the Whole, or of any committee of either House of Congress, is empowered to administer oaths to witnesses in any case under their examination.

To them is also given the power to summon witnesses, to insist upon answers, to compel the production of pertinent papers or documents, and to inflict punishment for recalcitrancy.

It is to the legislative branch of the Government, therefore, we must look for a searching inquiry into the conduct of the war in all its phases. This cannot be undertaken till Congress convenes in December next. In the meantime the President's Committee by devoting its inquiry to the volunteer camps may be able to throw some light upon the causes of their deplorable condition, and so be of service to the general betterment of the army camps as well as to the saving of many lives.

As the revelations from different quarters group themselves and the details of suffering, neglect, and incompetency become known the necessity of a searching investigation asserts itself with steadily increasing insistence. The Surgeon-General of the army has been charged with dereliction in not having had a sufficient supply of ambulances and medical and surgical stores during the Santiago campaign. In reply to this the Surgeon-General says that an abundant supply of everything needed in his department was ordered and would have been at hand had it not been for the utter failure of the Quartermaster's Department, which was responsible for the transportation. His charges have corroborative evidence in the facts that have been steadily coming to light indicative of the entire lack of system in loading the transports, and absolute ignorance of the requirements of such an undertaking. No one can be held responsible for not having had experience in such matters, but the least that can be asked of one who assumes this responsibility is that his experience shall have been such as to develop the faculties necessary to conduct work of that character with judgment, and that he shall have a reasonable acquaintance with the recorded experience of others. In Field-Marshal Lord Roberts celebrated book, "Forty-one Years in India," vol. 2, p. 28, in connection with the Abyssinian campaign we find recorded the following simple directions for loading transports:

I had often read and heard of the difficulties and delays experienced by troops landing in a foreign country in consequence of their requirements not being all shipped in the same vessel with themselves—men in one ship, camp equipage in another, transport and field-hospital in a third, or perhaps mules in one and their pack-saddles in another; and I determined to try and prevent these mistakes upon this occasion. With Stewart's permission I arranged that each detachment should embark complete in every detail; which resulted in the troops being landed and marched off without the least delay as each vessel reached its destination.

This precedent, of so simple a principle so successfully applied, if followed in the shipment of the Fifth Army Corps to Cuba would have provided the invading army with field- and siege-guns, commissary stores, ambulances, and medical and surgical supplies. Instead of which, as a matter of fact, the guns were packed in one ship, their carriages in another and their wheels in a third. The various parts of the ambulances were distributed throughout the fleet, and the medical supplies after primarily being entirely left behind at Tampa, were later stowed away in some ship and carried back and forth before they were finally landed. And for this the medical arm of the service is held responsible!

It has been suggested that the most judicious thing the President can do now is to abandon his project for an investigation and await the action of Congress, as the result of the work of his committee could not fail to be unsatisfactory to the country. In the management of the volunteer camps, however, there is a field for the inquiries of this committee provided they can be promptly undertaken and promptly concluded, for the purpose of informing the President how these camps have been managed and under whose supervision they have been placed. To mention one instance, they would have no difficulty in discovering that one of the most responsible medical positions in the entire army has been filled, not by the promotion of the best medical officer in the regular army—a man of medical and surgical experience as well as familiarity with camp-life and army methods—nor by a prominent physician taken from civil life who had a national reputation as a sanitarian, but by an obscure veterinary surgeon. The position referred to is no less than the chief surgeonship of an entire army corps. This veterinary surgeon has been the chief medical officer in charge of Camp Thomas at Chickamauga Park. His appointment was not made at the recommendation of the Surgeon-General of the army but as a result of political influence. Every medical staff officer in this entire army corps had to submit to the mortification of being *vis*é*d* and approved by this same veterinary surgeon. The responsibility for the sanitary arrangements and conditions of an encampment containing 40,000 men was vested in a man who, probably, never in his life gave one moment of serious reflection to the personal hygiene or sanitation of a body of men however small; a veterinary surgeon whose entire medical experience for the past fifteen years has consisted in doctoring horses, cattle, dogs, and cats. What else could be expected in a camp entrusted to the supervision of such a man than that it should have a reputation for filth and uncleanliness; that the water should be contaminated, and that the ranks should be ravaged by a frightful epidemic of typhoid fever.

THE CAMPS OF INSTRUCTION.

THE time has now come when we can dispassionately and impartially review the medical aspect of the military campaign now closing. We can clearly ascertain the causes of the misfortunes which have befallen the army and determine the responsibility for them. If we shall seem too severe in our strictures it is in deep humiliation that we are forced to record the shortcoming of those for whom, as members of our profession, we are disposed to find excuse; and we fall far short of painting an exaggerated picture.

The camps of instruction were for the purpose of familiarizing the volunteer with the duties of the soldier, train him for active service in the field, and particularly to bring him to a high physical efficiency. At the first call of the President each State entered into generous rivalry to furnish its quota of troops. Recruiting to the war standard was vigorously prosecuted, and mobilization was rapidly effected. Here we find the first cause of the inordinate amount of illness which has rendered the army practically useless. Adjutant-generals, owing their appointments to political favoritism or personal friendship, without military experience and devoid of even common sense, have imagined that the gathering together of masses of men in a hastily determined upon rendezvous was "mobilization" in the proper acceptation of the term. Thus it came about that a horde of

ununiformed, unequipped men, with some companies of the National Guard were sent into camp. While it is no particular hardship for a properly equipped soldier to bivouac in the inclement weather of our spring it was positive brutality, born of selfish conceit, to send unsuitably clad civilians to a camp which was unprepared and without sufficient tentage. An adjutant-general, so ignorant of the duties of his office that he assumed command of a portion of the National Guard while a ranking officer was present could be expected to do no better. The recruits should have been retained in the armories until such time as they could be properly equipped. The time might have been profitably employed in setting-up drills and instruction. These men were but obstacles to camp routine and that they were not incapacitated by unnecessary exposure was due to good fortune rather than to good management.

With the ignorance and incompetence of adjutant-generals begins the chapter of mismanagement which has wrecked as fine a body of men as ever assembled at the call of a nation's ruler. With the assigned reason that raw troops would be more quickly fitted for service in the tropics most of the camps were located south of Mason and Dixon's line. Facility of transportation to the supposed port of embarkation was also considered. It is claimed that not all camp-sites were passed upon by competent medical authority. It is to be hoped that this is true, for the surgeon who would certify that a suitable camp-ground is found where solid rock outcrops within three feet of the surface, so that the sinks could never be properly covered, certainly showed ignorance of one of the fundamental principles of camp hygiene. Nor indeed could a site be chosen upon the recommendation of a surgeon when the water-supply, polluted by one portion of the camp, was to be used by another section. The location of sinks, the disposal of refuse, and the proper policing of camps are matters for the exercise of common sense and good judgment.

An effort has been made to account for the acknowledged failure of the Medical Department by placing the blame upon the volunteer and acting assistant surgeons. To give point to the charge of incompetency and inexperience the latter are called "contract surgeons." To our mind there is no essential difference between a "contract," volunteer, or army surgeon. Many of the acting assistant and volunteer surgeons are men of greater executive ability, larger experience, and higher professional standing than their fellows in the army.

The difficulty in transporting supplies added to unhygienic camp discipline is responsible for the outbreak of fevers so extensive that every regiment upon the march left its trail of disease. That the surgeons alone, no matter how experienced or competent, could have kept a respectable sick percentage, is evident from a single instance coming under our observation. A permanent state camp occupied by a regiment of infantry and a battery of artillery after two months became so dirty that the odor of the sinks and of the kitchens was perceptible in almost any portion of the camp. It is said that there were seventy prisoners in the guardhouse, yet the camp was not properly policed. The men, in spite of two-months' drill, were not well set up and none showed the alertness and snap of the soldier. With a commanding officer who would be satisfied with such slovenly conditions the surgeon, whom we know to be competent and efficient, was powerless to maintain a respectable standard of health. In fact, at the time of inspection, an epidemic of typhoid fever had begun, and later extended so that the projected encampment of a home regiment became impossible. This was a camp of small size, near to markets, well equipped, containing men of far above the average intelligence, which became infected simply because it was not kept clean. What occurred in this instance undoubtedly came to pass in most of the camps. The causes of disease in the camps of instruction have been Falstaffian adjutant-generals, camps located for reasons other than military or hygienic, and finally camps dirty beyond the power of the surgeons to control. The Secretary of War has sought to offer excuse for the abuses existing by stating that in the work of creating an army of two hundred thousand men great difficulties were encountered. Had the Secretary created such an army some slender excuse might be accepted. The facts are that some two hundred thousand men, chosen for their good health and strong physique, are taken from their homes to be trained in the discipline of soldiers. Without having faced an enemy, without leaving the country, a regiment returns two hundred and sixty sick and marches through the streets of

the metropolis, scarcely a battalion fit for duty. The Secretary has created an army, but it is an army of the sick and dying.

ECHOES AND NEWS.

No Yellow Fever in Porto Rico.—Despatches from Ponce, dated September 19th, report that there are no more suspicious cases of yellow fever developing, and that the alarm incident to the early reports has entirely subsided.

Yellow Fever in Louisiana.—The Louisiana State Board of Health reported September 19th three additional cases of yellow fever in New Orleans, making four in all. No deaths. Also five cases in an Italian camp at Harvey's Canal, in Jefferson Parish.

Bellevue Appointments.— Commissioner Keller of the Department of Charities has appointed to the visiting staff of Bellevue Hospital, Dr. Henry C. Coe, gynecologist; Dr. L. Bolton Bangs, genito-urinary surgeon; Dr. B. Farquhar Curtis, surgeon; Dr. George D. Stewart, surgeon, and Dr. Egbert LeFevre, physician.

Yellow Fever in Mississippi. — The Secretary of the State Board of Health of Mississippi reported September 13th, "One case of yellow fever in Jackson. Already steps have been taken to stamp out and prevent the spread of the disease." No new cases have been reported from Franklin, Norwood, Holly Springs, Galveston, or Key West.

Married Women as Public-School Teachers.—The Board of Education of the Borough of Queens, New York City, at its recent session adopted resolutions to the effect that when a teacher gets married it will be considered equivalent to her resignation. It was also decided that hereafter the application of married women for positions as teachers must be endorsed by the unusual number of five members of the Board.

The Health of New York City.—In the report of the Health Department for the week ending September 17, 1898, appear the record of 169 new cases of tuberculosis and 145 deaths; typhoid fever, 209 new cases and 44 deaths; diphtheria, 102 new cases and 18 deaths. The increase in the number of typhoid cases is apparently due to the reception of soldiers into the hospitals upon their return from Montauk and the Southern camps.

Mortality among the Spanish Soldiers Returning to Spain.—The transport "San Ignacio" sailed recently from Santiago with 1000 Spanish prisoners. Of these, 123 died on the voyage. The high mortality among the troops returning in transports to Spain is ascribed by the Spaniards to the inhumanity of the Americans in compelling men in a critical condition to embark so that the Santiago hospitals could be cleared for the American sick.

The Transport "Vigilancia" Arrives at Montauk.—The transport "Vigilancia" which left Santiago on September 6th arrived at Montauk Point September 13th. She brought 320 passengers of whom 76 were sick and 15 ailing. Among those on board were 22 nurses, most of them colored and immune. This ship brought the last detachment of the Fifth Army Corps. Thirty sick soldiers and 8 nurses are all that remains of the army in Cuba.

The Fondness of Soldiers for Pie.—The soldiers of the Volunteer camps have developed an extraordinary fondness for pie particularly when recovering from typhoid fever, dysentery, or some other ailment which requires the greatest care in diet. Various devices have been resorted to to prevent them from gratifying their fatal longing, and recently the authorities at Camp Wikoff promulgated an edict forbidding the sale to soldiers of pies, pastry, or ginger ale.

The Louisiana State Board of Health. — In accordance with the law enacted by the last legislature requiring the Governor of the State to appoint seven representative physicians to constitute the State Board of Health, the following gentlemen have been selected and appointed: Drs. Edw. Souchon, President, Orleans Parish; H. S. Lewis, Orleans Parish; Chas. Goudel, Orleans Parish; J. P. Egan, Caddo Parish; W. G. Owen, Iberville Parish; R. L. Randolph, Rapides Parish; T. T. Tarleton, St. Landry Parish.

The Chicago Society of Internal Medicine. — A joint meeting of this Society and the Chicago Medical Society was held Wednesday evening, September 21st. Dr. John A. Robinson delivered a Presidential address. Dr. Daniel R. Brower, in an elaborate paper, opened the discussion upon "Acute Cerebral Meningitis," and Dr. Adolph Gehrmann read a paper on "The Results of Widal's Test in Typhoid Fever." The annual meeting will be held in January. The subject for discussion will be "Acute Articular Rheumatism."

The New Building of the Jefferson Medical College, Philadelphia.—Final plans for the new building of this institution have been approved by the trustees. The structure when completed will be one of the handsomest of the kind in this country and will cost about $250,000. The contract calls for the completion of the building by June 1, 1899. The building will contain the lecture-rooms, various laboratories, dissecting-rooms, etc. A unique feature will be the provision made for a gymnasium, reading- and billiard-rooms, and bicycle-lockers.

Typhoid Fever at Camp Meade.—The latest reports from Camp Meade indicate the presence there of more than one hundred typhoid-fever patients in the division hospitals. The sudden increase in the number of typhoid cases is attributed to the arrival of two New York regiments from Camp Black. The cases that developed at Camp Black in these regiments were of a mild type, but it is thought that the effort of breaking camp, making the long journey, and the change of location has changed the character of the disease to its worst form.

The Tax on Medicine Questioned. — A controversy has arisen in the Internal Revenue Bureau regarding the

proper classification of europhen, phenacetin, acetylene, lysetol, celoplien, pyretin, also sulfonal, trional, etc. The manufacturers of these drugs failed to place the proper revenue stamp upon them, claiming exemption as non-compounded articles. A test case is to be made as to the liability of these drugs to taxation, and the Collector at New York recently seized the place of business of an agent for these preparations. All the articles in question are to be stamped pending the decision of the court.

The Low Birth-Rate of Ontario, Canada.—The Montreal Anglican Synod recently held a discussion upon the low birth-rate in Ontario. It developed in the discussion that not only is the birth-rate low, but the marriage-rate is far below that of any other country of equal dimensions in the world. The reason for the former was ascribed by the ministers to causes over which persons have absolute control, and they insisted that the matter involves questions of grave moral responsibility. The low marriage-rate was accounted for by the fact that so many women are employed in stores and in other occupations, and the migration of young men from the rural districts to the cities.

A Positive Danger.—Professor Vincenzi is said to have been making investigations regarding the purity of certain holy water used in a popular church in his native city. He found that one drop of the water taken on Saturday while people were applying it to lips or brow, when spread on a gelatin sheet, yielded within forty-eight hours about 2300 colonies of bacteria. On Sunday when the holy water was in more constant use the professor could not estimate the innumerable colonies, but his tests proved that there were diphtheria bacilli among them, and cases of diphtheria in Sassari at the time emphasized the revelation.—*Boston Medical and Surgical Journal.*

Cornell University Medical School.—This institution has succeeded in procuring a plot of land on the west side of First Avenue, reaching from Twenty-seventh to Twenty-eighth streets, and will commence immediately the erection of a five-story building to cover the entire plot. The building will contain not only the Medical College but also the Dispensary. The cost of the building and land is estimated at $600,000. It is expected that the new building will be ready for occupancy in October, 1899. In the meantime the college will occupy the Loomis Laboratory and the building formerly occupied by Bellevue Hospital Medical School. The benefactor of this new institution is Colonel Oliver H. Payne who has bestowed upon it the lavish endowment of $1,500,000.

Diplomas Made Handy.—The *Medical Press* has found recently in an Irish daily contemporary a congratulation to a member of the Irish Constabulary on the fact that he has become a fully qualified medical practitioner through the agency of the Queen's College, Belfast, and also, an intimation that another police constable is following his example and hopes soon to be found in "The Medical Register." Commenting upon this our contemporary says: "If the Royal Irish Constabulary permits the absence of an officer for five hours a day during four academic years, we can only express regret that we do not belong to the service. If, on the other hand, the teachers of the Queen's College and of the hospitals in Belfast are distributing sham certificates for sham attendance to enable persons who are not *bona fide* students to go in for examination, it is our duty to call the attention of the profession to the matter."

Fifth Annual Meeting of the American Academy of Railway Surgeons.—The preliminary program of the Fifth Annual Meeting of the American Academy of Railway Surgeons, to be held at the Auditorium, Chicago, Illinois, Wednesday, Thursday, and Friday, October 5, 6, and 7, 1898, is as follows: Wednesday, at 10 A.M.—"Anesthesia," R. H. Cowan, M.D., Radford, Virginia. "Traumatic Injuries of Peripheral Nerves," D. S. Fairchild, M.D., Clinton, Iowa. "Injuries of the Genital Organs," Milton Jay, M.D., Chicago, Illinois. Second Session at 2.30 P.M.—"The Radical Cure of Hernia," W. J. Mayo, M.D., Rochester, Minnesota. "Concealed Meningeal Hemorrhage," H. Reineking, M.D., Sheboygan, Wisconsin. "The Interment of Ericsen," W. J. Galbraith, M.D., Omaha, Nebraska. Thursday, October 6th, at 9.30 A.M.—"Physical Examination for Railway Service," J. F. Pritchard, M.D., Manitowoc, Wis. "The Hygiene of Railway Injuries," G. P. Conn, M.D., Concord, New Hampshire. "Conservatism in Railway Surgery," H. Hatch, M.D., Quincy, Illinois. Fourth Session at 2.30 P.M.—President's Address, "The Higher the Order of Railway Surgery the Greater the Protection to the Employe, the Passenger, and the Company," R. Harvey Reed, M.D., Rock Springs, Wyoming. "Convenient First Dressing in Fractures, with Samples," E. H. Trickler, M.D., Cutler, Ohio. Friday, October 7th, at 9.30 A.M.—"Surgical Treatment of Some Varieties of Disease of the Prostate and Seminal Vesicles," G. E. Benninghoff, M.D. The following Fellows of the Academy have promised papers but up to date have not furnished subjects for the same: Drs. A. D. Bevan, Chicago, Illinois; Allen Staples, Dubuque, Iowa; LeRoy Dibble, Kansas City, Missouri; C. K. Cole, Helena, Montana; George W. Crile, Cleveland, Ohio. An executive session will be held daily at the opening of the meeting. D. C. Bryant, M.D., Secretary, Omaha, Nebraska.

CORRESPONDENCE.

THE PRIORITY IN THE "RIGHT TO LEFT AND LEFT TO RIGHT" OPERATION IN HYSTERECTOMY FOR FIBROID AND PUS CASES.

To the Editor of the MEDICAL NEWS.

DEAR SIR: December 1, 1894, I published in the MEDICAL NEWS a paper on "A New and Rapid Method of Dealing with Intraligamentous Fibromyomata." The claims I made for this operation were that by it time was saved, the uterine artery on the side of the nodule was secured beneath the nodule by a ligature applied from the vaginal side after the uterus had been cut loose from

one side and tilted over the nodule, wounding the ureter was avoided, and without splitting the capsule of the fibroid.

October 9, 1894 (before publishing this paper), I read a paper before the New York State Medical Association on "Hysterectomy in Pus Cases," in which paper I had a crude drawing showing the application of double ligatures *en masse*, placed upon one uterine artery in this manner, namely: from the vaginal side after tilting the uterus over to one side. The method necessitated removal of the cervix, the uterine artery stumps being ligated *en masse*.

At a stated meeting of the New York Obstetrical Society, December, 1894, I presented eight specimens, some pus cases, and others, pus with fibroids. The reports were not so much to illustrate the features of my operation, but rather to promote discussion regarding the propriety of the abdominal or vaginal route in operating upon these cases. Hence, these reports did not state positively that the ligatures were applied from the vaginal face in Cases II. and III.; but in Case IV. I say: "The left uterine artery was secured from the vaginal side, the fibroid nodule peeled out of the broad ligament and the uterus, together with the left adnexa, removed." I further state: "The other (feature of interest) is the removal of the specimen after the uterine arteries were secured. This latter method I have adopted now a number of times in these old inflammatory lesions where the union between bowel and pus-tube seems so intimate as would endanger the former if I attempted to remove them in face of the oozing which accompanies the separation of tissues before the vessels are secured."

So then, in October and December of 1894, I reported cases of fibroid and pyosalpinx removed by progressive ligature down one side and up the other, or "left to right and right to left." I am constrained to make claim to priority for this operation because nearly two years after the first application of this method I find in the *Bulletin of the Johns Hopkins Hospital*, February-March, 1896, a description of almost identically the same operation. The claims made by the Johns Hopkins Hospital are: (1) Saving of from sixty to eighty per cent. of the time in the enucleating stage of the operation. (2) The ease with which intraligamentary myomata and myomata beneath the pelvic peritoneum may be enucleated. (3) The ease with which inflammatory masses posterior to the broad ligament may be enucleated by attacking them from below after dividing the cervix. (4) The control of a displaced ureter on the side last opened up, keeping it out of the way of injury by the simple mechanism of the operation.

All of these claims in the *Bulletin* I had made nearly two years before. The sole points of difference are: that I do complete hysterectomy, while the Johns Hopkins Hospital staff leave the cervix; and I ligate the uterine arteries *en masse* while they ligate in continuity. The *claims* for the two operations are identical. As my report antedated theirs nearly two years, I claim credit for the procedure, which is known here as Kelly's operation and in France as "la méthode Américaine."

I regret very much being compelled to make this statement, and in its utterance I beg that none will think I seek to blame any one. Perhaps it is my own fault that this unpleasant situation has arisen for the *Johns Hopkins Hospital Bulletin*. I might have prevented it had I more liberally advertised and more beautifully illustrated the operation. The only agencies at my command were the New York Obstetrical Society, the MEDICAL NEWS, The New York State Medical Association, and my own poor pen.

Very truly yours,
WM. R. PRYOR, M.D.

NEW YORK, September 14, 1898.

PRIORITY OF THE SUGGESTION OF SALINE INFUSION IN SHOCK.

To the Editor of the MEDICAL NEWS.

DEAR SIR: On reading my article on "Post-operative Saline Infusions," published in the MEDICAL NEWS of September 18th, I am struck with my omission therefrom of all reference to Dr. Dawbarn of New York, to whom the world is indebted for the first suggestion of the intravenous use of normal saline solution as a preventive of shock. Dr. Dawbarn also first demonstrated the fact that for such purpose the temperature of the solution should be high—115° to 118° F.—and thereby perfected one of our most valuable and reliable therapeutic measures in such cases.

I am so averse to doing Dr. Dawbarn injustice, even by a "sin of omission," that I ask you to publish this statement in your next issue of the "NEWS."

Very sincerely yours,
EUGENE BOISE.

GRAND RAPIDS, MICH., September 15, 1898.

MONTAUK POINT AS A HOSPITAL CAMP.

To the Editor of the MEDICAL NEWS.

DEAR SIR: You ask my opinion as to the relation between the number of sick at Camp Wikoff and the hospital accommodations provided therefor. Premising that the opinion is formed not upon full official data but only upon such partial reports as have appeared in the newspapers and upon personal observation of a few of the regiments, I take pleasure in replying.

The camp was established for the reception of the Fifth Army Corps, then at Santiago, which numbered about 22,000 men. Several of its general officers had insisted, in a letter published in the papers, in demanding an immediate withdrawal of the entire army from Cuba because of the prevalence and rapid spread of fever among the men; they stated that 90 per cent. of the force were, or soon would be, unfitted for duty by illness. Assuming that half of the men thus affected would require hospital treatment, this estimate called for hospital care for 10,000 men. The Government began by erecting a general hospital with 500 beds and a detention hospital which ultimately had 600 beds. The general hospital was soon enlarged to the capacity of 2000 beds, and in the second week of September the four division

hospitals, each with 150 beds, were constructed; at the same time half of the general hospital and almost all of the detention hospital were taken down so that the hospital capacity of the camp was reduced at that time to about 1000 beds. Its maximum was 2000 beds, and was reached late in August. According to the scanty reports which appeared from time to time, the maximum of troops in camp at any one time was about 20,000, and was reached about September 1st. It was rapidly reduced during and after the second week of September.

The hospitals were made of floored wall tents with slight wooden frames; construction was easy and the supply could have been increased almost at will in a day or two; the supply of nurses was ample; more were offered than were accepted; that of orderlies or male nurses was apparently sufficient; that of physicians appeared to be ample. The Red Cross furnished $14,000 worth of supplies and I believe many of the nurses.

In the first month more than 6000 patients were received in the general hospital. Almost all of them came directly to it from the transports or through the detention hospital. The average stay was less than a week probably, for the capacity was only 500 at first, and there were from 400 to 900 vacant beds after September 5th. During the rush of arrivals on transports, from 150 to 300 patients were discharged daily to make room for the new ones, and many of them were sent to hospitals in neighboring cities. Many were discharged as "well" either to their regiments or on furlough, the latter drifting in large numbers into the city hospitals a day or two after their discharge. Not a few, I have been told, were discharged against the protest of the attending physicians, and it is certain that large numbers of them still needed hospital care, and would not have been discharged when they were had it not been for the necessity of making room for others whose needs was thought to be greater. The published mortality, of about 150, is no measure of the severity of the diseases, for it does not include those who died after removal or were discharged as "well," although they and their companions are counted among the number treated. On these facts alone it is evident that the hospital accommodations were inadequate and it is probable that a number of the deaths among those who were thus discharged were due to this withdrawal of hospital care. If the condition of the troops in camp is considered this inadequacy becomes still more apparent, especially if we include among those needing hospital care those who, because of present or past illness, were unable to eat or digest the army rations, good and wholesome as they were.

That there were many really ill in the regimental camps, men with typhoid, malaria, or severe diarrhea, is beyond question, but I have no means of estimating this number. I saw some such in every regiment I visited. I have had several such in the Hudson Street Hospital (men who came to the city on furloughs and were picked up by the ambulance), and many such have been cared for in other city hospitals. Why were they not taken to the general hospital? I do not know. Probably because at first there was no room for them, and later, because they preferred the freedom and companionship of their camp, and thought they would do as well there as in the hospital. Numerous as I believe these cases to have been, they were far outnumbered by the "ailing," those who may or may not have been on the sick-list, large as that was, who were miserable, had occasional chills, could not eat, could not work. The 8th Ohio left camp, 900 officers and men, with a sick-list of 261. The commanding officer of a regiment of regulars told me his sick list was 139 out of a total of 320. A regimental surgeon told me he had been called on to furnish 15 men for guard duty at the hospital; he picked up the best men in his regiment and before they had been two hours on duty two of them had been put to bed in the hospital. One of the papers quoted a regimental commander as saying that he could muster only 8 men fit for duty in response to a call for a detail of 24. We are all familiar with the pitiful stories told by so many eye-witnesses, of men dropping by the roadside as the troops marched from the transports to their camps; of the sick at the Montauk station, in the trains, and at Long Island City. These were the "well" men, or at least, those who did not have hospital treatment.

I would not claim that all these men, if at home in the city would receive hospital care, but they did need special food as well as medicine. Unfortunately, the Army routine makes no provision for such a condition outside of the hospital. These were men whom the War Department had collected and maintained, and drilled for months, some of them for years, in order to have an effective force of which it might at any moment have urgent need, and ordinary prudence and economy, to say nothing of humanity, should have prompted it to take fitting care of them. It was quite possible, even easy to do so. In default of special tents, those which sheltered them in the camps could have been grouped as regimental or brigade hospitals, and at the most, only extra nurses and orderlies, and the special food would have been required. Even the machinery and routine therefor could have been found in the department. The failure to do so must, I think, be deemed neglect on the part of those who were charged with the making of proper and adequate provision for the force.

LOUIS A. STIMSON, M.D.

NEW YORK, September 15, 1898.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

RETIREMENT OF PROFESSORS ON AGE, COMPULSORY, OR OPTIONAL, AND WHEN?—ACUITY OF VISION AND ABSENCE OF BALDNESS AMONG GERMAN UNIVERSITY MEDICAL PROFESSORS—THE OPENING OF THE NEW PATHOLOGICAL MUSEUM AND THE TWENTY-FIFTH ANNIVERSARY OF THE CHARITÉ ARZTE—THE PASTEUR TREATMENT IN BERLIN—THE PADERSTEIN STIPENDIUM FOR '98 AND '99.

BERLIN, September 12, 1898.

THE recent retirement of Professor Gruber of Vienna, on the completion of his seventy-first year, recalls the question so often discussed here in Germany of making

professorial retirement obligatory in German universities at a certain age. While, thanks mainly to the efforts of the elder Rokitansky, a law exists in Austria by which professors are retired at seventy, an additional year, the Ehren or honor year being allowed by ministerial indulgence and custom now, no such law exists in Germany. As a consequence the holder of the professor's chair to whom the blessing of years is given occupies his position on into the eighties.

While in some cases the enforced retirement at seventy-one, as is true of the distinguished Vienna otologist just now, deprives a university of some years of active professional life on the part of distinguished members of its faculty, as a rule the period of really good work is past at seventy and retirement is certainly advisable. There is no doubt that the system of non-interference in German universities has in many cases, even in great universities, left important chairs in the hands of men on whom the weight of years bore too heavily to allow of them either giving the proper encouragement to scientific advancement and initiative on the part of younger men in their department, or of suitably organizing on a modern basis the teaching that fell to their lot. I venture to say that there is not a single professorial chair in a German university occupied by a man beyond his climacteric of three score and ten, no matter how distinguished his services to science or to education have been in the past, whose retention of his position has not proved a serious hindrance to educational progress. There are cases well known where even at present special departments in great universities are wofully neglected because an old, though perhaps distinguished professor, retains a charge that should have been laid down with advancing years. So long as human nature remains our present human nature, however, the confession of senility incident to a voluntary retirement can scarcely be expected and least of all of men who have had the consciousness of their superiority to others during a long life. The necessity then for a law or custom in the matter is evident. The question is a most delicate one and the period at which retirement should be made obligatory by no means easy to agree upon. The age at which men are at the acme of their intellectual power has always been the subject of disagreement. Aristotle puts it at forty-nine and the recent graduate thinks this entirely too old, while his distinguished professor thinks it altogether too young. Not even the omniscient Aristotle ventured to suggest when men entered on the decline of their intellectual powers.

The late Professor Rokitansky the younger, whose early death at fifty-one in his professorship at Graz deprived the scientific world of a distinguished medical man expressed some very definite opinions on the subject shortly before his death. It was mainly owing to his distinguished father's influence as I have said that Austria owes its present laws, as to the enforced retirement of university professors at seventy-one. The younger professor Rokitansky, who had been especially interested in the question and in an excellent position to study the working of the law, urged that the age limit should be made still younger. He advocated the framing of a law requiring retirement to the rank of emeritus professor, though with the emoluments of ordinary professor at the age of sixty-five. Only where a special faculty unanimously asked for the continuance of an individual in a professorship might the ministry or executive university authority permit service after the age of sixty-five and then for not more than two years at most.

Of course this would seem to be going to the other extreme and such a law would deprive many a German university of the services of great teachers. In Berlin, for instance, it would retire two of the great clinicians, Leyden and Gerhardt, at once, and the third, Senator within the year. These are not the only lights of German medicine who would suffer eclipse and there is scarcely a German university but would feel it. Yet the proposer of the law must have thoroughly realized this and must have been deeply imbued with the necessity for active interference in a matter of serious import to have suggested the seemingly early retirement. Meantime, however, the question remains open and an important one it would seem to be, not only of interest here in Germany, but everywhere in educational circles where the necessity has been felt of some delicate, graceful, and courteous way of shelving talent, not when its usefulness was entirely gone, but when the beginning of its decline brought with it the inevitable deficiency in initiative that makes it unsuitable for the direction of new scientific work, and incapable of imparting that enthusiasm which constitutes the best part of education.

According to a recent article in the *Deutsche Medicinische Press* of Berlin the university professors and lecturers in the medical faculties of Germany are far above the average of mortals in the matter of acuity of vision and absence of baldness. As these are two qualities not usually attributed to medical men generally and especially not to those whose devotion to science has brought them distinction in a professorial career, some of the data of the article seems of special interest.

Out of 210 professors and scientific investigators in the medical faculties of the various German and Austrian universities only 61, less that 30 per cent., wear glasses. This is, one cannot help but think, a considerably lower percentage than obtains in America; statistics in the matter would be not only interesting, but would have, I should imagine, a very practical value for ophthalmologists now that it is so usual to attribute refraction defects to over use of the eyes so much more than to a natural optic weakness. If there is any significance in a certain interrogation that is sometimes put, yet does not seem to demand an answer, who ever saw an ophthalmologist who did not wear glasses? Perhaps it would be well not to include too many of our distinguished eye specialists in the list of well-known physicians if the American statistics are to be really representative and significant. Perhaps, too, it should be the eye whose refraction required no artificial aid that should be set to the work of making out the statistics so as to be sure that lacunæ did not slip into them because of any lack of acuity of vision on the observer's part.

As to baldness the statistics are even more surprising, as

171 out of 210 professors, etc. (nearly 85 per cent.) are still in the possession of practically all their hair and in its original color. Only 21 are bald, only 18 are gray. All of them, of course, are beyond middle life, most of them being well on in years. One is tempted to wonder how many of our friends the gynecologists, whose hair troubles are proverbial in Europe as well as in America, are included in the list.

The writer in the *Medicinische Press* attributes the good eyesight of the doctors and the conservation of their hair to the fact that most of the men who distinguish themselves in medicine in Germany are men on whom great physical vitality as well as mental power has been conferred by Nature. Most of them reach an advanced old age despite years of the strictest application to science and retain their mental powers to the very end. It is getting to be more and more generally admitted in all lines of intellectual work that genius, or at least talent, is practically always associated with a natural substratum of intensest vitality. *Mens sana in corpore sano* is not only a maxim for practical guidance in the matter of physical exercise in after life but is an original condition on which serious scientific work is dependent for its success primarily. Hence, the normal retention of even unimportant natural advantages despite a life of serious application.

Already the first inklings of a noteworthy medical celebration to be held in Berlin at the beginning of next year are coming to light. The Charité Arzte, the association of consultants and residents at the Charité Hospital, Berlin, will celebrate their twenty-fifth anniversary early next year. The new Pathological Institute, at least the Pathological Museum Department, is to be finished by that time and is to be formally opened then. As many of the prominent medical men in most of the German universities have at some time or other in their career been in service at the Charité the assemblage of members will form a distinguished reunion. The celebration will practically take on the character of an inauguration of the New Charité, of which this will be the first department opened. The occasion is the twenty-fifth anniversary of a most important medical society and the initiation of that new era which, in a completely remodeled Charité, is to assure Berlin the position she holds, of European center for medical teaching, and is expected to inspire a good deal of enthusiasm for the celebration and the event will be one that will attract more than passing notice in the medical world.

The special feature of therapeutics in Berlin continues for the moment to be the treatment of rabies by the Pasteur method. Within six weeks after the opening of the new department some dozen of cases had been under treatment. They are practically all cases from the German provinces near the Russian border. They are not, however, the result of any sudden irruption of the disease into German territory. When such cases occurred before this they were sent either to St. Petersburg or Vienna. The expressions of those in charge of the department continue to be those of eminent satisfaction. The dangers of the treatment once so much insisted on in Germany are now considered to be minimal or non-existent. Already movements are on foot for the establishment of similar departments in other university cities.

The medical faculty of the University of Berlin announced at the end of the summer semester that the Paderstein stipendium for the next year was conferred on Dr. Max Koch, a graduate of Berlin. His graduation thesis, of which the stipendium is practically a mark of recognition, was reviewed in these columns just after its publication. Its subject, "The Connection between Atrophy of the Glands of the Gastro-intestinal Mucous Membrane and Pernicious Anemia," is of living interest just now and the review of the immense literature to date, with the actual observations of the writer himself make it of great practical value though his conclusions are but those that have already been gradually gaining acceptance that the changes noted and for a time thought so important are only adventitious, the result not the cause of the anemia.

SELECTION.

THE USE AND ABUSE OF MIDWIFERY FORCEPS.[1]

I.—By R. Milne Murray, M.A., M.B., F.R.C.P. (Edin.), Lecturer on Midwifery and Diseases of Women, Edinburgh School of Medicine; Assistant Physician, Royal Maternity Hospital.

Surgical Midwifery.—I think I am right in stating that the selection of this subject for discussion arose out of the able and trenchant address delivered by the former President of this Section at the Montreal meeting last year. In that address Dr. Sinclair drew attention to what he considered the close relation between many gynecological troubles and the over-frequent and injudicious use of the forceps.

The address contained much to give the reader pause, but its general tenor may be gathered from a brief quotation from it which I venture to make: "Midwifery has during the same period," says Dr. Sinclair, "become also largely surgical—too surgical, and a thesis which I shall endeavor to maintain to-day is, that gynecology has become so largely surgical as the direct result of surgical interference in midwifery practice; the accoucheurs are the providers of material for the gynecologists. . . . The term surgical is employed here with almost exclusive reference to the midwifery forceps."

I am not using too strong an expression when I say that this amounts to an indictment of the present practice of midwifery all over the world; and coming as it did from the Presidential Chair of this Section, it must have caused much searching of heart on the part of accoucheurs on both sides of the Atlantic.

But it was not only on the general practitioner that the

[1] The discussion held by the Section on Obstetrics and Diseases of Woman of the British Medical Association at its recent meeting in Edinburgh, slightly abridged from the report as it appeared in the *British Medical Journal*. A condensed abstract made by our special reporter was published in the MEDICAL NEWS, August 13, 1898. The subject is so important and the opinions of so many eminent men are given that the discussion is deemed worthy of fuller presentation.—Ed.

strictures of the address reflected. If the practice of midwifery were aberrant, no small part of the blame must lie at the door of the teachers of obstetrics. If the practice were loose, the teaching must be greatly at fault.

It could not be supposed that such a statement could be made by one in the position Dr. Sinclair occupies without due deliberation, because it directly implied that one section of those whom he was then addressing was engaged in providing employment for the others, either by reason of gross and culpable error of judgment or by direct malpractice.

The Value of the Forceps as a Surgical Instrument.—I shall best fulfil my duty to-day by raising points for discussion, or suggesting the lines which the discussion should take, rather than by attempting any necessarily inadequate deliverance on the whole subject.

I begin by asking, "What is the special value of the forceps as a surgical instrument?" To Baudelocque is due the statement that the midwifery forceps is the most valuable surgical instrument that has ever been invented, and "with this statement," says Dr. Sinclair, "we are all more or less in agreement." I think there are few here who will cavil at my reply to the question I have just put, if I say that the special value of the forceps is that it enables us to shorten the suffering and diminish the risk of childbirth. If it is to justify the claim of Baudelocque it must accomplish these results in a sensible proportion of cases, because if it is only to be employed at rare intervals to diminish the suffering or even save the life of an occasional mother, while we should cherish it as a valuable component of our armamentarium, we would scarcely place it in the position claimed for it by Baudelocque. Apart, however, from the question of the frequency of its proper use, I may take it for granted that its value consists in the power it gives us on certain occasions of shortening the duration of labor, of diminishing the dangers of the mother, and greatly increasing the safety of the child.

But when we turn to the scope of the instrument and ask what are the indications for its use, we reach highly debatable ground. I daresay if the question were put to twenty individual members of this meeting there would be given twenty distinct answers, all more or less divergent, and some diametrically opposed. Perhaps the one side would best be represented by the answer Dr. Sinclair would give, while that of his anonymous friend, who startled him with the statement that his forceps cases amounted to seventy per cent. of his whole midwifery practice, would adequately represent the opposite; and these two, along with the other eighteen, would give one more instance of the many-sided character of the human mind!

When Forceps Should Be Used.—I shall make no attempt to analyse or classify those hypothetical answers. It will be more useful if I try to lay down a general principle which ought to guide us in seeking the indications for the use of this instrument. I think I can be sure of taking you all with me when I say that *a direct indication for the use of the forceps arises whenever—and only whenever—we are assured that the danger of interference has become less than that of leaving the patient alone.* So simple is this statement, that to some it may seem a mere truism, and to be scarcely worthy of deliberate enunciation. Nevertheless, I believed it is, in the case of some practitioners, just one of those pious opinions which are assented to the moment they are stated, and the moment after practically ignored.

I venture to think it is more than a mere truism, and that it ought to be kept more constantly before us and more strictly acted on than it sometimes is. For let me point out that it implies that the use of the forceps, in practically every case, is a matter of individual judgment. There is no accepted set of rules which can be applied to each emergency, and which will decide for us in each case whether we are to act or to hold our hand. It is for this reason that the question of the proper use of the forceps is often so difficult. Much more than in most surgical operations have we to consider in each case, not one, but many circumstances. If we discover an abscess, or a cancer, we deal with them at once by opening or excising them according to fixed principles, and by methods which have been determined by experiment and settled by experience. But the operation of the forceps comes under a different category. A fetal head and an ovarian tumor cannot be dealt with on the same lines. It is sound practice to remove the latter as soon as it is detected, but the mere presence of a fetal head in the pelvic cavity is not an adequate reason for its summary removal. There are many things to be considered, many things to be taken into account—the state of the passages, the efficiency of the pains, the condition of the child—ere we can justify any effort to supplement or supersede the processes of Nature. Each case must be decided on its merits, and in every case when the question of forceps arises, we must ask, "Is it safer to act or to wait?" We have no justification for interference until we have decided that the danger is in waiting, nor, let me add, in failing to act when we have decided that the danger is in delaying. It is this necessity for individual judgment in every case which renders the employment of the instrument a matter of grave responsibility.

Premature Use of Forceps.—From what I have said, it will follow that a certain number of the instances of improper use or abuse of the forceps are due to errors of judgment—the instrument is employed when it should not be used; or else it is not used in cases when it is indicated. It was to the frequency with which the first error is committed that Dr. Sinclair specially devoted his address last year, and no doubt a very substantial proportion of the instances of the abuse of the forceps comes under this category. But this does not by any means represent all the cases of misuse of the forceps; for while injury is inflicted in many cases by the premature use of the instrument, and in a smaller number by undue delay in its employment, a very large part of the injury to mother and child—and thus a large part of what may be properly termed the abuse of the forceps—is due to faulty technic.

I may perhaps best put it thus: (*a*) The forceps are often used at the wrong times. (*b*) They are sometimes not used at the right times. (*c*) They are often badly

used at both times. The danger of the forceps operation, apart from the risk of septic infection (which, of course, is common to most operations), may be summarized thus:

1. The mother's parts may be bruised, lacerated, or otherwise injured by mechanical violence.

2. The too sudden emptying of the uterus may be followed by imperfect retraction, and, consequently, dangerous hemorrhage.

3. The fetal head may be unduly compressed, lacerated, or otherwise damaged.

Now, in spite of all that has been done and is being done to diminish the risk and suffering of disease by anesthesia, antiseptics, and other means, there seems a lingering doubt in the minds of some as to whether the abolition of the pain and suffering of labor would be an unmixed blessing. This seems to me to be a survival of the same barbarous instinct which prompted the so-called religious objection to the use of chloroform in labor, and is as unworthy of respect. For myself I have no such scruple, and were I able to do so with safety I should gladly abolish every pain after the first, and reduce the duration of labor to a bare minimum. But unfortunately this is not practicable. Physiological labor consists of a series of phenomena which require time for their development; and a grave abuse of the forceps consists in their employment in such a way as to interfere with the proper sequence of the normal physiological events.

Forceps in Undilated Os.—This leads me to consider a group of cases in which we have the most striking illustration of the use of the forceps at the wrong time, namely, their application through an undilated os. There is, no doubt, a small minority of cases in which such an application is, for special reasons, justified and even demanded; but these are few and far between, and the disastrous results following their use in many of these cases are only too familiar to obstetricians. The statistics of this practice, obtained from the results of the Rotunda Hospital under Dr. Johnston's mastership, are in themselves a commentary on the dangers both to mother and child.

Spasmodic Rigidity.—I would draw particular attention to the dangers involved, because I feel sure there is a group of cases falling under the term "undilated os" which is not so generally recognized as it should be, and the non-recognition of which seems to me to account for more damage to the mother's parts than we may at first admit to be likely. Every one is familiar with, and no one can well overlook, the ordinary form of undilated os, in which, either from early rupture of membranes, narrow pelvis, malpresentation, or other cause, the os remains for hours in a half dilated state. If, in spite of such a condition, the use of forceps is for some reason, good or bad, decided on, the operator recognizes the condition, calculates the risk, and, it is to be hoped, does what he can to minimize or obviate that risk to the utmost of his power by careful management. But there is another form of undilated os quite as unsuitable for the forceps operation as this, and which is the more dangerous because it is not always recognized. I am convinced it accounts for the occurrence of by far the larger number of cases of lacerated cervix. For while the delivery of the head through the variety of undilated cervix referred to is always a difficult and often a dangerous operation, nevertheless, it can be done, and is done in many cases, given a proper instrument, the requisite skill, and abundant patience. It is not so with the variety I now wish to consider. Here is the sort of case I refer to. A woman has been in labor for some hours; probably the membranes have ruptured early, and dilatation is slow. Opium possibly has been given, or chloroform has been used, and after a time an examination, made in the absence of a pain, shows the os soft, flabby, and apparently nearly the size of the child's head. The head is probably well down in the cavity, and lying fairly well for the application. Here, then, seems a suitable case—a long labor, a tired woman, perhaps, if I may whisper it, a wearied accoucheur, and most important of all, an os, if not dilated, at least dilatable. A little more chloroform is given, and then without any difficulty the forceps are slipped over the head and, of course, inside the os. By this time a uterine pain, excited by the manipulation, begins, and if the os is now examined it will be found spasmodically contracted round the head and forceps, and not more than half its former apparent size. Unfortunately, it sometimes happens that an examination is not made, and traction is commenced with results which do not require description here. The case is one of partially dilated, spasmodically rigid os, and may be described in physiological language as an example of uterine incoordination, or, popularly, as a uterine stammer. The os during an interval is soft, flabby, and easily stretched; during a pain it becomes tense, hard, and greatly narrowed.

I have several times been asked to see patients in consultation, where the attendant thinking the os was fully dilated, had ruptured the membranes, and found after uterine pains had begun again, that the os was less than two-thirds dilated. The same mistake had arisen—the os was examined in the intervals, and its spasmodic rigidity overlooked. To use the forceps here and to treat the case as if the os were dilated or dilatable is one of the gravest, and, I fear, only too common examples of their abuse. On account of the tension and thinness of its edge, very slight efforts of traction will tear the cervix into the vaginal roof, inflicting frightful injury.

Secondary Inertia.—I need not detain you by dwelling on the dangers of the application of the forceps to a woman in a condition of secondary inertia, and to the almost inevitable results in the shape of deficient retraction and hemorrhage in the third stage and *post-partum*. And I do not doubt that other instances of the use of the instrument at the wrong time will be sufficiently emphasized by one or other of those who follow me in this discussion.

Failure to Use Forceps When Necessary.—Let me then say a word about the second point I raised; namely, that the forceps are sometimes not used at the right time.

Whatever material damage or injury may be inflicted by the injudicious use of the forceps, there is one injury—once common enough, and now rarely to be seen—namely, vesicovaginal fistula, whose disappearance is in great measure a result of the earlier, perhaps often premature, application of the forceps. No more striking instance of the beneficent use of the forceps can be adduced than that which we may point to in the almost total disappearance of this frightful injury. Most men nowadays take care that the long, tedious, grinding pressure of an ill-placed head, on a contracted or otherwise modified pelvis, is never allowed to occur, and the consequent necrosis and sloughing are thus largely avoided.

But I cannot help thinking that the reasonable reaction which has shown itself in many schools against the too frequent use of the forceps may in some measure diminish our vigilance in this matter, and that from an unwillingness to interfere we may unwittingly render possible an undue amount of maternal bruising and other damage. I could not find a better illustration of what I refer to than I do in the "Rotunda Report" for 1896-97. Here there is a record of 56 forceps cases, and in the summary of the indications of their use I find that 45 were treated by forceps on account of "delay in the second stage of over four hours." In the absence of further statistical detail I cannot express an opinion as to whether the forceps in these 45 cases were rightly or wrongly employed, whether it might not have been better to have interfered sooner than the fourth hour in some cases, or to have waited even longer still in others before artificially finishing the labor. The report simply states that "forceps were applied in cases of delay of four hours in the second stage with material benefit to the mother and greater safety to the child, and we consider the results obtained, more particularly as regards the life of the child, amply justify us in not delaying longer" (p. 10).

The objection I would make to a statement such as this in an authoritative report is, that it gives us an impression that the element of time is the primary determining factor. I am quite at a loss to understand why, for example, we should wait in every case for four hours after the os is dilated and when the pains are not advancing the head. To my mind the latter point is the *crux*. If I could assure myself that after dilatation of the os the advance of the head was blocked—either by the size of the head, the resistance of the canal, or the feebleness of the pains—I should not wait a moment before using the forceps. I could not assure myself that this was the case without waiting a certain time, but I am perfectly certain that in many cases I should reach absolute assurance long before four hours had elapsed. If I am certain of this in one hour, why should I wait three more? What do I gain, and what does the patient gain, by my watching her enduring two or three hours of further misery and suffering? If the head is in the brim and shows signs of descending, I shall wait till it descends, because the operation of forceps is easier in proportion to its descent. If the head is in the oblique diameter and shows signs of rotating, I shall certainly wait till the rotation is complete, because the application of forceps is simplest and the delivery safest when the head is in the anteroposterior. But if neither of these things occurs from fault or failure of any factor, I see nothing to be gained, but much to be lost in waiting after I am certain that progress is at an end. The danger of interference is then less than the danger of waiting.

There are many wise obstetric aphorisms, but none wiser than this: "Wait till you see what Nature can effect—not what she can endure." No one need imagine that this can be read as an apology of meddlesome midwifery. As long as Nature is preparing or opening the passages, and molding or advancing the passenger, she is doing what she can do better than any of us, but she sometimes fails, and it is because she fails that Baudelocque's commendation of the forceps is "one with which we are all more or less in agreement," because by its means we have saved women hundreds and thousands of weary hours of useless suffering and preserved countless children alive. Let it not be supposed that I am traversing the practice of the Rotunda Hospital. The report at my disposal gives me no facts on which I could base my criticism; what I suggest is that the mode of stating the grounds of interference is essentially misleading, and I wish to enter my protest against the idea which it conveys that the time element alone is a proper basis for such interference.

If I am asked when, under such conditions, I should apply forceps, I should make a reply in words which I first heard from the lips of my respected teacher and your distinguished President, and which I have never forgotten: "When the passages are in a fit state and Nature fails to advance the head, then I should apply the forceps."

Forceps in Occipitoposterior Positions.—I must leave to others the indication of other cases in which the forceps might be used with advantage when their use is avoided or delayed. But I should like to direct attention to one group of cases in which the forceps might be employed with greater discrimination than is, I think, sometimes used. I refer to occipitoposterior positions of the vertex. We all know that in such cases, when flexion is well marked and when the pains are efficient, descent and forward rotation is the most usual ending, while in those cases in which flexion is deficient, descent is difficult and backward rotation the rule. My own view and teaching in the matter is this—that when flexion is deficient, as shown by the ease with which the bregma can be reached, the sooner forceps are applied after the os is dilated the better. In view of the practice generally recommended in regard to these cases this may seem heroic if not rash. But I confess I have little faith in the attempt at manual rotation; my experience of it in these cases is that it is futile, and on theoretical grounds I have never understood how it can be anything else. When it succeeds it seems to me almost certain that rotation would have occurred without it. For if natural rotation is the result of the action of the pelvic floor on the advancing head, I cannot understand how twisting the head in the canal can develop it when it is defective. If in rotating the head we brought it to bear more firmly on the floor, I could understand that a sound principle was involved,

but we can scarcely claim that we do this. Everything, however, depends on the forceps employed. With the axis-traction forceps, more especially if slightly modified, we can develop flexion and secure rotation in nine out of ten cases, and in the tenth would probably have done so too had we used them soon enough.

Faulty Technic.—Finally, the forceps are abused by being badly used; not only when they should not be used, but also in cases in which their use is indicated. Now I am convinced that to these faults of technic, as I may call them, are due not only the greater number of minor errors in the use of the forceps, but likewise some of the gravest examples of maternal and fetal injury. I venture to refer to a few of them—some of them I regard as of most importance.

The first fault of technic to which I ask attention is one which is still too common. It consists in not employing what is indubitably the most efficient instrument. If a workman chooses for his purpose a tool which is less efficient than some other which is available, he may execute the work, but he does so either less perfectly than he might, or does so with an unnecessary expenditure of time and energy. So if the problem to be solved in the forceps operation is to extract the child with the expenditure of as little force as possible, we fail in that problem if we do not use the instrument which enables us to economise our force to the greatest extent. That this instrument is one constructed on the principles first laid down by the late Professor Tarnier has been long taught by every member of the school to which I belong. Professor Simpson has illustrated the value of the axis-traction forceps by saying that a man who has once used them would as soon think of reverting to the old forceps as a man who could keep a carriage would think of conducting his practice on foot.

When I was a boy I was more or less familiar experimentally and otherwise with a piece of mechanism, the prototype of the modern bicycle appropriately and familiarly known as a "boneshaker." It possessed wheels, a backbone, a saddle, and a steering-bar, just like its descendant, and among other things it had a tire which, if it had no other advantages, was at least durable and puncture-proof. It certainly was a very different affair from the machine on which we see young and old, rich and poor, gliding along noiselessly and almost without effort at five to fifteen miles an hour. Now I should be inclined to say that a man is just as likely to revert to the old instrument after having used the axis-traction forceps as he would be to give up a good bicycle of 1898 for a boneshaker of the early Seventies'. The main argument advanced in favor of the older forceps is its simplicity, and this argument is quite as much in favor of the boneshaker, for its construction was complicated neither by ball-bearings, spring saddles, nor pneumatic tires. But I have heard a practitioner declare that he could do as much with the old forceps as another could with the axis-traction forceps. I would as soon believe that the average man on the primitive bicycle I have referred to could ride as far or as fast, and with as little fatigue, as one on a modern machine.

The Axis-traction Forceps.—To object to the instrument that it is complicated is an argument with which, I confess, I have little patience. That a couple of rods and a handle-bar should present a serious difficulty is an argument scarcely worthy of a grown man.

I may take it that practically it is universally admitted that axis-traction is of great advantage at the brim, and with regard to its efficiency there I need not detain you. The pleasure I have of knowing that many of those I address constantly employ and strongly advocate these instruments is saddened by the knowledge that there are some who listen to me who are not yet convinced of their efficiency, save at the brim. But I am certain of this, that those who have systematically used the instrument in all their forceps cases will bear me out that for once they have proved their efficiency at the brim, they have done so ten times in the cavity and twenty times at the outlet. They will speak of the security of the grasp, the absence of dangerous compression, the ease of extraction, the delicacy with which the proper axis can be ascertained and followed, and the safety to the soft parts which it ensures. They will perhaps, most of all, commend the instrument on account of the facility with which it produces or permits of the production of rotation.

Compare this with the deliverance on the axis-traction forceps I find in one of the recent text-books on midwifery. "The use of the axis-traction forceps is practically confined," says the author, "to pulling the head through a contracted brim; when the head has passed into the cavity it is no better than the ordinary kind. It is only of use, therefore, to pull the head through a somewhat smaller brim than can be passed by the latter. In cases where the difficulty is so great as this, it is in all probability better to turn." This reduces Tarnier's work to a vanishing quantity. And again, in another part of the same book, I find, "they all (that is, axis-traction forceps), however, have the same disadvantage of compressing the head during their application."

I confess it is difficult for one who has used these forceps for nearly twenty years to treat such comments seriously. As to the question of compression, I do not believe that the compression of the head by the axis-traction forceps is as much as ten per cent. of that inflicted by the ordinary forceps. Any one can prove to himself that after the blades are in position and in contact with the head, one-half turn of the screw is all that is necessary to keep them in position. Not infrequently the screw slips out of its catch during traction, and I have delivered many cases in which the screw was off all the time the forceps were in the cavity. When the head is in the cavity, the pressure of the walls, the inward pull of the rods, and the cephalic curve of the blades keep the latter in perfect security on the head. With the ordinary forceps, it is obvious that the harder you pull the more you grip the handles—not in order to hold the head, but to prevent the handles from slipping from your grasp; nevertheless, the head bears the brunt of the pressure.

As to the efficiency of the instrument in the cavity, I have said all that I need say, and as to removing the forceps when the head has reached the perineum, for myself

I should as soon think of leaving the patient in the third stage of labor as of removing the forceps before complete delivery of the head. I am prepared to maintain that in axis-traction forceps, properly constructed and properly used, we have not only a means of accomplishing delivery in cases of delay with safety and success, but by their means we are able to avoid laceration of the pelvic floor in cases in which this would unavoidably occur if left to Nature. For I have long held that deep anesthesia, combined with the skilful use of the axis-traction forceps, is the best treatment for rigid perineum.

The Guiding Principle in Applying the Blades.—The second fault of technic to which I shall direct attention is in connection with the application of the blades. Of course when the head is at the outlet and fully rotated, the application can only be faulty from gross carelessness; but when the head is in the cavity and still in the oblique diameter, a very faulty application is often made. It is still largely the teaching and the practice of the British schools to apply the forceps as far as possible in relation to the pelvic transverse without reference to the position of the head. Now when the head is high in the cavity, or even low in the cavity and not rotated, I am convinced that this is wrong. The result of this practice is that we obtain a more or less oblique grasp of the head, and it follows that, since the blades tend to rest on somewhat sharply curved portions of the head, one or the other inclines to slip off during application, and the difficulty of locking is notorious. Equally notorious is it that the vicious practice of trying to rectify this by twisting the blades into position is a source of danger to mother and child. But apart from this, after locking is effected and traction begun, one of two things follows:

1. The head as it descends rotates, and in doing so throws the forceps into the opposite oblique. This usually happens with axis-traction forceps when rotation is favored. If delivery is effected without removing and readjusting the forceps, extensive damage to the outlet will follow.

2. The head descends without rotating, and engages the outlet in the oblique. This often happens with the older forceps, and is even more disastrous than the former.

I venture to think that the practice of the French school is much sounder. The forceps should be applied to the biparietal diameter of the child's head wherever situated, and then, as the head descends, rotation will bring the blades into the transverse diameter just as the head enters the anteroposterior, and the head, forceps, and pelvis will present proper relations at the outlet. I feel sure that extensive damage to the lower part of the vaginal canal—especially internal laceration of the perineum—is often caused by oblique position of the head or of the forceps at the outlet. The application of the forceps to the side of the head may require more care than the other methods, but we are there to take what care is necessary for the benefit of the patient.

I need not dwell on the objectional results of jerky irregular traction. A uterine pain begins almost imperceptibly and increases in intensity by fine gradations. So should an effort of traction. Only by this can we bring the head and canal into proper relation, and only by this can we develop rotation and minimize the danger of pressure.

The Mode of Traction.—Every year I become more and more convinced of the advantages the axis-traction forceps give us in protecting the perineum from injury caused by undue delay, or laceration caused by faulty mechanism. The procedure I adopt is as follows: As soon as the vault touches the floor the forceps are held between the finger and thumb of the right hand, while the left is placed over the fundus. I may say at once that I never in any circumstances "support the perineum." The left hand enables me to control the retraction, to detect the beginning of a pain, and often to aid the action of the forceps by efficient pressure. I press the chloroform as far as will keep the patient quite still. Extraction is effected by gentle pressure on the traction-bar, the rods and shanks being kept just touching. With certain exceptions I act as far as possible only with a pain taking care always that traction is effected in such a way as to maintain the advance of the suboccipito-bregmatic diameter. In this lies the secret of success, for by means of these forceps we can restore or maintain the relation of this diameter to the outlet—a relation which is often disturbed by peculiarities of the pelvis, and more often by alteration in the shape of the head, caused by molding or swelling of the scalp, associated with long and difficult labor.

There is one group of cases, however, which form a marked exception to the rule of extracting with a pain. Not infrequently we find in elderly primiparæ that every uterine pain, when the head is low, is accompanied by a spasmodic action of the muscles of the floor, which for the time narrows the vulvar orifice and throws the perineum into a state of intense rigidity. It is in cases of this type that we find instances of perineal laceration. In such a case I deepen the anesthesia and carefully avoid traction, save in the intervals of pains. Delivery is simple and easy thus, for the orifice is often wide enough when not spasmodically contracted. This is another instance of incoordination, and must be treated in this special way. Without forceps such cases will continue in labor for hours, and as the spasm only passes off when the pains are checked by chloroform, this alone is not enough.

Conclusion.—Whether the forceps are to be an engine of disease and death, or a means of protection alike to mother and child, will depend upon whether they are used with a seeing eye and an understanding heart—upon whether the obstetrician is prepared to put aside all adventitious considerations, "the uneasiness of the gossips"—even the demands of the patient, most of all his own convenience, and interfere when, and only when, he has deliberately assured himself that the risk of interference is less than the danger of waiting. If this principle is unswervingly followed and carried out with reasonable skill, Baudelocque's commendation will still hold good, and the forceps will maintain their high place among the products of the ingenuity of man.

II.—W. S. PLAYFAIR, M.D., LL.D., Consulting Obstetric Physician, King's College Hospital, and Emeritus Professor of Obstetrics in King's College.

Over-action and Reaction.—Dr. Playfair said that he had always believed that the surgical development of gynecology was due to such things as ovariotomy, removal of the appendages, hysterectomy, and the like, which no one could say were produced by the accoucheurs; but granting that it was only a harmless exaggeration, it was none the least necessary to reply to it. It must at once be admitted that Professor Sinclair's address would do a great deal of good. It would warn against excess, it would teach medical men to be more careful than many had been. But did that touch the principle? There was no improvement in medicine which was not open to the accusation of having been abused. Take trachelorrhaphy, which Professor Sinclair himself cited as an example of a great improvement in gynecology. Surely the use in England of that occasionally valuable operation had been greatly hampered by the ridiculous way in which it had been overdone in a sister country. Again, with the very useful "rest cure," had not the abuse of massage made that very useful remedy stink in the nostrils of right-minded people? So with the most recent fashionable remedy—the "Schott cure"—and many others which could be named. All this should warn against abuse, but it should not be used as an argument against proper use. Most of those present were probably entirely unaware of the frightful evils which followed the old practice. His old friend and fellow student, Professor Simpson, would remember how common in their student days was that awful accident "vesicovaginal fistula," now hardly ever seen, its abolition being the direct result of modern practice. Again, Dr. Sinclair had not even alluded to one of the great glories of modern midwifery—the almost total abolition of craniotomy, formerly so common as to be an every-day procedure. Surely this was an enormous gain. Who could say how many lacerated cervices and torn perinea should be taken to be equivalent to even one human life saved from the deadly perforation? At any rate he, Dr. Playfair, must insist that his book on midwifery should not be blamed for any such over-frequent use of the instrument, since he had most carefully safeguarded his teaching on this point.

III.—W. J. SMYLY, M.D., Late Master of the Rotunda Hospital, Dublin.

The Time to Use Forceps.—Dr. Smyly said that safety in the use of the forceps lay in adhering as closely as possible to their employment under favorable conditions, that is, when the head presented and had passed the brim by its greatest transverse diameter, when the os was fully dilated or dilatable and the membranes ruptured. Sometimes it was necessary to employ the instrument under less favorable conditions, but then the indications must be more definite than when, as under the conditions indicated, they were employed merely to save suffering. Under unfavorable circumstances they should only be employed in case of danger to the mother or child. The high forceps was, therefore, an operation not to be taken lightly in hand, and the importance of time in molding the head to the brim should not be forgotten; a head might come through with molding which could not have been brought through with forceps at an earlier stage. Time was of no account in midwifery nor any indication for the use of forceps.

IV.—PROFESSOR FEHLING of Halle.

Frequency of Forceps Operations.—Professor Fehling, speaking as a teacher, said that the chief mistake of students and practitioners was to employ forceps in the absence of strict indications, hence the bad lacerations seen were due to the increasing frequency of forceps operations; while, as Hegar and Cullingworth had shown, the mortality in childbed had not been diminished. In ordinary cases three points must be insisted on: the head must be under the brim, well rotated, os dilated; if so, then the forceps might be employed when there were indications in the condition of mother or child. If there were any danger for one or another, it was justifiable to operate in the absence of these three conditions. He wished to emphasize the advice that students should be taught not only on the phantom, but in the labor-ward. At Halle, during the last four years, the forceps had been used in 290 out of 3000 cases, but only 55 of these were in the clinic (3.5 per cent.); the greatest number occurred in the polyclinic. Two mothers died from eclampsia, two from rupture, which had occurred before the forceps were applied; of the children, 6.2 per cent. were still-born. Most of the operations were done by the students, the others by the assistants. Professor Fehling felt sure that to have done one operation under the supervision of the master prevented the young physician from making mistakes later on in practice.

V.—SIR WILLIAM PRIESTLY, M.D., M.P., Consulting Obstetric Physician, King's College Hospital.

Meddlesome Midwifery.—There had been of late years such improvements in the construction of forceps and in the recognition of the suitable conditions for their use that obstetricians might well feel more confidence in their value, and there could be no doubt that a great saving of life and of injury had been effected both to mothers and children.

The danger perhaps now was lest the use of forceps should be pushed too far, and it was well that conservative influence should be exercised to restrict them within proper bounds. He was glad to recognize that the reader of the paper gave a timely warning in this respect. It was still true that "meddlesome midwifery" might be bad practice, but this did not necessarily mean that forceps must not be used more frequently than formerly, always supposing that the best forms of instruments were selected, and that the conditions at the time of their application were such that there was the smallest possible risk of injury to both mother and child.

To apply forceps before the passages were sufficiently dilated, and especially when the os uteri was imperfectly dilated or rigid, was to incur great risk of laceration, and there was then so much more force to overcome that the attempt might well fail. It was quite true, as had just been stated, that the natural forces would often mold the fetal head to the maternal passages in such way as

to facilitate delivery when forceps applied above the brim had failed to effect delivery.

VI.—WM. STEPHENSON, M.D., Professor of Midwifery in the University of Aberdeen.

Preventive Midwifery.—Use and abuse must be taken together, and the second term made to limit that intended to be included in the first. Frequent use and abuse was the idea. Frequency in the use was the great advance in midwifery during the latter half of this century. It was well to remember that the movement originated in the ranks of the profession, and not from the teachers. He would prefer that the general practitioner would be heard to-day, and not the teacher. He could not accept the rule adopted by some leading teachers—that instrumental aid was to be given only when there were symptoms of danger to mother or to child, or to both. It was the old cry: Wait till Nature begins to fail. The true principle was: Aid whenever you can without deranging the mechanism, so as to avert symptoms of danger. But Dr. Murray had fully vindicated the present frequent use against the fallacies and strictures of those who would have men return to the custom of a hundred years ago. Dr. Stephenson further discussed the point that with the axis-traction forceps there was a delicacy of manipulation, which a skilled man, while retaining the use of the ordinary handles, could exercise more especially in aiding rotation in O.-P. positions. He found it, however, impossible to discuss that question in full on that occasion.

VII.—ARTHUR V. MACAN, M.B., F.R.C.P., King's Professor of Midwifery, Trinity College, Dublin.

The Principle of Administration.—I would first wish to explain Dr. Playfair's observations about Dr. Labath's statistics of his cases of craniotomy during his mastership of the Rotunda Hospital, which he said were so numerous that it was not considered worth while to keep any statistics of them. This is not so, but each master takes the records of his mastership away with him, and unless he has published them no one else can supply them.

Next as to the dictum that Dr. Milne Murray has given us, namely, that the forceps should be applied when the danger of delay is greater than the danger of delivery by the forceps. This seems quite simple, and at once gains our assent. But when we try to translate it into practice we find that it requires great skill and experience to know when the danger of the operation is less than the danger of delay. It is, therefore, my practice to impress on my students the fact that the chief danger of delay lies in want of antiseptics, and that if they were careful of the latter the want of the former is less important.

Personally I consider that the greatest triumphs of the forceps are the cases that require the least traction. If the force of resistance is the least greater than the driving force there can be no progress. Here the slightest traction with the forceps will effect delivery, and this seems to me the greatest triumph.

Before going on to the axis-traction forceps I would like to point out that the ordinary double-curved forceps can be used—indeed, ought always to be used—as an axis-traction instrument. Traction in the direction of the handles of the double-curved forceps is always wrong, and traction by both hands, one at each end of the handle, drawing the latter in a series of parallel lines toward the chest of the operator, is essential to making the instrument an axis-traction instrument. If the axis-traction use of ordinary double-curved forceps were properly taught it would be quite unnecessary for the instrument-maker to stamp on one of the blades of the forceps, "Left, lower, first." This seems to me to presuppose a very low standard of intelligence and knowledge of the instrument in the man that is about to apply them.

Nor can I agree with the view that the forceps should not be applied to the head until the largest diameter of the head is past the brim. For in such cases, if the head is already fixed to the brim, and the indications for delivery are urgent, the only alternative is craniotomy. Indeed, in cases of flattened pelvis it is not infrequent to feel the head being flattened inward and springing outward, according as the traction is applied or relaxed, and on examining the head afterward we find a spoon-shaped depression on the child's head, caused by the pressure of the sacrovertebral angle against the head. The axis-traction forceps which we use in Dublin is that introduced by my friend Dr. Neville, which, as far as I can see, is quite as effective, and much more simple and easy of application, than any other axis-traction forceps with which I am acquainted.

VIII.—J. M. MUNRO KERR, M.B., F.F.P.S.G., Assistant Professor of Midwifery, Glasgow University; Assistant Physician, Glasgow Maternity Hospital.

Mode of Grasping the Head.—I desire, owing to the enormous number of questions involved in such a discussion as the present, to confine myself entirely to one point and it is to an abuse, or rather misuse, that I wish to refer. It is the general teaching, and it will be found in the text-books of Galabin and Playfair, that forceps should be applied without reference to the diameter of the child's head. Now, I consider this bad teaching, because there is a lack of exactness in it. The forceps should be applied with reference to the diameter of the child's head. If the head is low down in the pelvis, it is always possible to grasp the head transversely. If the head is high up it is more difficult; with care, however, even in these cases the head can be grasped nearly transversely, and the more nearly transversely it is grasped the better. If it be admitted—and I think it will be—that the more nearly transversely the head is grasped the better, then the general teaching I have referred to is defective, because it will be a chance whether or not the head is grasped in the best manner possible. Further, if cases of flat pelvis be considered, it is of the very greatest importance to have regard to the child's head and grasp it exactly anteroposteriorly. A slight departure from such a grasp will very readily result in injury to the child and injury to the mother from the forceps slipping.

IX.—J. W. BYERS, M.D., Professor of Midwifery and Diseases of Women and Children, Queen's College, Belfast.

Cases Requiring Forceps.—Professor Byers thought that all would be agreed that the indications for the use of the forceps had been well put by Dr. Milne Murray: "Wait until you can see what Nature can effect; don't interfere until she fails." When danger arose either to mother or child, it was desirable to act at once; but there were other cases in which there was no doubt that, even in the absence of distinct evidence of danger, all other conditions being favorable, the use of the forceps was justifiable. He was entirely in favor of the use of axis-traction forceps, and it was only fair to Dr. Milne Murray to say that it was to this type of instrument he alone referred in the discussion. He was with those who said that full dilatation of the os was necessary before using the forceps, but in certain exceptional cases (as in eclampsia or sometimes in aged primaparæ) they might be called for earlier. As to using forceps at the brim, he preferred to apply them rather than to turn in a flat pelvis. As to the use of the forceps where the head had come to the perineum, he preferred not to take them off, but to continue their use until the head was fully delivered, but the point was to let the head come out not, as the majority of books taught, by extension, but in a gliding manner.

X.—W. JAPP SINCLAIR, M.D., F.R.C.P., Professor of Obstetrics and Gynecology, Victoria University, Manchester.

Unskilful Use of Forceps.—Dr. Sinclair expressed modified approval of the axis-traction forceps, but could not imagine a time when the ordinary long forceps would be discarded in favor of the axis-traction instrument. His address in Montreal had been misunderstood to some extent, and he proceeded to speak of Dr. Playfair's criticisms. He reiterated a statement of his position in regard to the use of forceps and the teaching of midwifery. There was at least sufficient ground for reconsidering current practice, and the forceps must be used unskilfully as long as they were used by men who had not received exact teaching so as to diagnose the position of the head before the instrument was used.

XI.—ROBERT JARDINE, M.D., Physician, Glasgow Maternity Hospital.

The Axis-traction Forceps in Contracted Pelves.—Dr. Jardine said that in Glasgow they had to deal with a very large number of contracted pelves. Last year they had ten per cent. of these cases requiring major operations. Like Professor Byers, he believed axis-traction forceps gave a better chance to both the child and mother. He had delivered children weighing 8½ lbs. alive through a true conjugate of three inches, and he always used the forceps in preference to turning. There was one precept to which he attached importance—never to turn after failure with axis-traction forceps. He had never seen a child saved in this way, but he had had cases of rupture of the uterus brought into the hospital which had been caused by this. Craniotomy was not an obsolete operation as some of the former speakers had intimated. In cases of this kind it should be done. In regard to putting on the instruments before the os was fully dilated, he said there were a few cases in which it was necessary, but such cases were very few. If the patient were under chloroform, it was, as a rule, possible to dilate manually. Theoretically the transverse grasp of the child's head was the right one, but practically it was often impossible, and he had seen over and over again that when the child was delivered the grasp was oblique. With a good instrument like Dr. Milne Murray's, it mattered not what the grasp was, as there would be no damage done to the head.

REVIEWS.

A SYSTEM OF MEDICINE BY MANY WRITERS. Edited by THOMAS CLIFFORD ALLBUTT, M.A., M.D., Reguis Professor of Physics in the University of Cambridge. Volume VI. New York: The MacMillan Co., 1898.

THIS volume, the last but one in this superb system, is devoted to the respiratory organs, the pleura, and the circulatory system. The diseases of the arterial system are omitted because of a delay on the part of Dr. Welch of Baltimore on "Thrombosis and Embolism." The editor, in a rather humorous way, apologizes for this author's delinquency, which is attributed to his work, never to be forgotten, against the antivivisection bill now pending in Congress.

If anything this volume is even better than its predecessors. A detailed review is impossible in these columns, but a few of the leading articles will be mentioned. Dr. Pye-Smith writes in a scholarly way on pneumonia, giving the minutiæ of its bacteriology in the clearest possible manner. The veteran Dr. Samuel West has an article on intrapleural tension full of clinical value. Professor Foster has written a lucid article on the general macroscopic and microscopic features of the blood, and the editor contributes monographs on chlorosis, functional diseases of the heart, mechanical strain of the heart, and aortic diseases. An interesting contribution is that of Dr. Thomas Oliver on the effects of electric currents of high pressure, the author attributing deaths by electricity to sudden cessation of the heart's beat. Dr. Robert Muir's paper on leucocythemia is admirable and is beautifully illustrated.

The volume is marked by literary excellence as well as scientific accuracy and well bears out what we have previously emphasized—that Allbutt's system is a classic of the highest grade.

THE JOHNS HOPKINS HOSPITAL REPORTS. Report in Gynecology. Baltimore: The Johns Hopkins Press, 1898.

THIS volume contains but two articles. One is an exhaustive analytic study of seventeen hundred cases of abdominal section from the standpoint of intraperitoneal drainage, by Dr. J. G. Clark. This work is already familiar to readers of gynecologic literature, and it is necessary only to mention the author's conclusions, based on wide reading, abundant clinical experience, animal experimentation, and autopsies. Mechanical drainage he condemns and offers in its place so-called postural drainage obtained by elevating the foot of the patient's bed, salt solution of a normal strength having been introduced

into the abdominal cavity before this has been closed. The saline fluid, gravitating toward the diaphragm where it is absorbed, drains the abdomen of fluids which are the result of operative interference or of disease which it is impossible to remove by mere mechanical means. For the details of the technic the reader should refer to the original article which is well worth the careful study of every abdominal surgeon.

The second paper is by Dr. James E. Stokes, on "The Etiology and Structure of True Vaginal Cysts." The author points out the difference in structure and descent of cysts found in the posterior wall, the lateral walls, the vault of the vagina, and shows that such cyst may arise from inclusion, from embryonic peculiarities, or from the glandular structure of the vagina. The paper is well illustrated by histologic drawings.

THE OFFICE TREATMENT OF HEMORRHOIDS, FISTULA, ETC., WITHOUT OPERATION. By CHARLES B. KELSEY, A.M., M.D., Late Professor of Surgery at the New York Post-graduate Medical School and Hospital. New York: E. R. Pelton, 1898.

AFTER reading this little volume, one wonders why these short clinical lectures were ever put into book form. The first of them tells what most surgeons know, that the packing, and sometimes the curetting of fistulæ, will lead to a cure. The second emphasizes the fact that the rectal specialist should be an abdominal surgeon and capable of performing plastic operations on the female, which is laudable. The third and last speaks of the abuses of colostomy and urges that such operations shall always be done after due deliberation, which is not remarkable. The author takes occasion as well, to refer to his own low mortality after this operation, which is commendable.

DISEASES OF THE STOMACH. A text-book for practitioners and students. By MAX EINHORN, M.D., Instructor in Clinical Medicine in the New York Post-graduate Medical School and Hospital; Visiting Physician to the German Dispensary. Second revised edition. New York: William Wood & Company, 1898.

THE first edition of Einhorn's "Diseases of the Stomach," published less than two years ago, was received with such favor that it at once occupied the niche among authoritative text-books on this side of the Atlantic that Ewald's treatise on the same subject holds in Germany. This second edition differs but little from its predecessor, although a few slight additions and alterations have been made.

The book is divided into fourteen chapters, the subjects being treated in a thoroughly scientific manner and sufficiently in detail to allow of the student obtaining an exact working knowledge of each. The first chapter deals with the anatomy and physiology of the stomach, and then follow in turn others on methods of examination, diet, local treatment, organic diseases with constant lesions; functional diseases with variable lesions; abnormal conditions with reference to size, shape and position; nervous affections, and the condition of the stomach in diseases of other organs.

Einhorn's work in connection with direct electrization of the stomach is so well known that the chapter on this subject will be read with particular interest. His very large experience with the method, as perfected by himself, and the almost uniformly good results obtained, have placed the procedure in the list of those upon which the general practitioner as well as the specialist can rely with complete confidence in those cases in which it is indicated.

It is unnecessary to refer more in detail to Dr. Einhorn's book. This second edition will but enhance its popularity, and it is safe to assume that the edition will be exhausted within a period as short as was the first.

THERAPEUTIC HINTS.

For Fissures of the Nipple.—

The following method of treatment is recommended as effecting a cure within three or four days:

Cleanse the nipple with a one-per-cent. bichlorid solution and dry with sterilized cotton. Cover fissures with thiol-collodion (ten per cent.), avoiding the openings of the milk-ducts. Order the use of a nipple-shield until healing is completed.

For Tropical Dysentery.—According to observations made on the island of Ceylon, ATTYGALLE testifies to the satisfactory results obtained by the administration of chlorid of ammonium every four hours, with the addition, if indicated, of opium and cannabis indica. The patients were given a diet of milk and arrow root. In the majority of cases the stools ceased to be bloody, and the colicy pains disappeared after three or four days of this treatment.

Tonic Pills in Locomotor Ataxia.—For the tonic treatment prescribed after a course of mercurials the following formula is used by ERB:

℞	Ferri lactatis . . .	gr. xl–gr. lxxx
	Ext. cinchonæ . . .	ʒ i–gr. lxxx
	Ext. nucis vomicæ . .	gr. v–gr. xv
	Ext. gentianæ, . . .	q. s.

M. Ft. pil. No. XL. Sig. One or two pills three times a day after meals.

Salicylic-Acid Ointment in Acute Rheumatism.—Since a small amount of salicylic acid is absorbed through the skin, its external application is recommended as a valuable adjunct to internal medication, and as a substitute for the latter when improvement begins. Its advantages lie in the relief afforded the stomach and in the suggestive action of the local treatment. The turpentine should be omitted from the following formula as soon as the superficial epidermis is destroyed:

℞	Ac. salicylici Ol. terebinthinæ Lanolini	aa . . .	ʒ iiiss
	Adipis . . .	q. s. ad.	℥ iii.

M. Ft. ungt. Sig. External use. Cover with a dry bandage.—*Sternberg-Lodz.*

ORIGINAL ARTICLES.

THE ABUSE AND DANGERS OF COCAIN.[1]

BY W. SCHEPPEGRELL, M.D.,
OF NEW ORLEANS, LA.

WHEN cocain was first brought to the attention of the medical world it was heralded as an unalloyed blessing to mankind, and one which would revolutionize surgical methods. In some respects this expectation has been realized. The extraordinary effects of cocain in surgery, especially in the minor branch, have surpassed even the most sanguine hopes, and its application has become such a routine practice that we but little realize that fifteen years ago this drug was practically unknown. In many cases in which a general anesthetic and its attending danger would not be admissible, and in which the patient is unwilling or unable to tolerate the physical pain of a minor operation, this useful alkaloid allows the necessary surgical procedure to be carried out without pain or inconvenience, although not without a certain element of danger, as was claimed by those who first employed it.

In no part of medicine has cocain been of more service than in the treatment of diseases of the upper respiratory passages. This is in a great sense due to its ease of application, as the mucous membrane absorbs the various solutions of this drug easily, an absorbability which is less in the throat than in the nose but in each location sufficient to obviate the necessity of a submucous injection. Not the least value of cocain in the nasal passages is the contractile effects on the erectile tissues, which enables the operator to inspect the field more thoroughly, whether for examination or for the necessary manipulation for operative procedures. Many pathologic conditions no doubt would escape observation but for this useful effect of cocain.

While admitting, then, that cocain has proved a great benefit to medicine and surgery, and that it has contributed not only to the comfort of the patient but also to the success of the physician by enabling him to operate more easily and thoroughly, it cannot, however, be said to be an unalloyed blessing. In fact, so fully have surgeons realized the evil effects which the indiscriminate use of cocain has caused that many believe it has been productive of more harm than good. This was recently illustrated by the remarks of some of the speakers who expressed this opinion in a discussion before the American Laryngological, Rhinological and Otological Society at its meeting at Washington during May, 1897. As these men have had unusual opportunities for noting the good and evil effects of cocain, their opinion is certainly entitled to much consideration.

That the danger of the toxic effects of this alkaloid is not fully understood is demonstrated by the fact that in the large majority of cases in which the effects are serious or even fatal no drug to counteract its toxic effects has been at hand. These toxic effects are by no means rare, as is demonstrated by a study of the literature of this subject, and when it is realized that by far the greater number of fatal cases do not find their way into medical literature it can be more fully understood that the application of cocain is not without its attending danger. The knowledge of this should cause one to make the same preparations in administering cocain as when a general anesthetic is used, as the difference of danger is but relative. The agents for this purpose which will be found most useful are nitrite of amyl, nitroglycerin, atropin, whisky, ammonia, and digitalis. The most rapid method of relief, and one most easily applied, is the horizontal position, and this should be resorted to at the first appearance of toxic symptoms.

The toxic effects vary according to the amount of cocain used and the susceptibility or idiosyncrasy of the patient, the latter, as in the case of morphin, being the most serious consideration in the application of this drug, as it sometimes develops in patients in whom it is least expected. In all these cases the element of fear should be considered, with its depressing effects upon the heart and circulation, thus predisposing the patient to the toxic effects. The application of cocain should, therefore, be tentative, this applying especially to hypodermatic injections in which the action of the drug cannot be controlled when once it has left the syringe. On this account, also, cocain should never be used in the nasal passages in the form of a spray; it should be applied by means of a small pledget of cotton so that the administration can be discontinued at the appearance of the first toxic symptoms.

Among the symptoms due to cocain poisoning are extreme pallor, profuse perspiration, unconsciousness; frequent, feeble, irregular and intermittent

[1] Read before the Orleans Parish Medical Society, May, 1898.

pulse; dizziness, nausea, in some cases great agitation, and occasionally loquacity; more rarely, blindness, deafness, lividity, muscular rigidity, a feeling of impending death, convulsive twitchings, paralysis, and convulsive or suspended respiration. The earliest symptoms should be carefully noted and counteracting measures at once instituted. When the symptoms are sufficiently urgent the administration of medicines by the stomach should not be relied upon, but the more rapid and efficacious method of hypodermatic injections at once resorted to. The majority of symptoms disappear quickly or within a few hours after the application of the cocain, but they are sometimes prolonged for several days. Among the latter may be noted obstinate headache, insomnia, hallucinations, numbness of the extremities, and prostration.

The writers who have recorded the evil effects of cocain in their practice are sufficiently large in number, although probably small in proportion to those who have not reported their unfavorable cases. Among those may be mentioned Ricke,[1] Maurice Schmidt,[2] Paul Heymann,[3] B. Pitts,[4] D. Mowat,[5] Moizard,[6] Booth,[7] A. W. Addinsell,[8] Szuman,[9] and S. Mitchell.[10] A case of chronic convulsions which lasted three hours in a ten-year-old child is reported by Jacoby,[11] and in one case reported by Haenel[12] the epileptiform convulsions lasted for five hours.

The literature of cocain anesthesia demonstrates the fact that death has occurred from its administration in many instances. Whether this fatal result is due to the amount of cocain administered, to a peculiar idiosyncrasy of the patient, to omission of proper antidotal or restorative measures, or to the lack of their prompt application, is naturally difficult to determine. Many cases, probably, are due to a combination of these causes. In a case reported by Abadie[13] death followed an injection of a 5-per-cent. solution of cocain for an operation on the eyelid. There was loss of consciousness within ten minutes, the respiration stopped, and the face became cyanosed as if from asphyxia. There was partial resuscitation after great effort, but death followed the same evening.

The urethral injection of cocain has been a fruitful source of fatal results. In a case reported by Simes[14] the patient was a man aged twenty-nine years in whom a 20-per-cent. solution of cocain was introduced into the urethra by means of a long-nozzled syringe which passed about four inches into the canal, the object being to perform an internal urethrotomy. Toxic symptoms at once developed, the muscles of the face twitching, the eyes staring, pupils dilated, frothing at the mouth, face much congested, respiration labored, and finally epileptiform convulsions. The respiratory function was labored, the action of the heart became irregular and slow, and the entire surface of the body cyanosed. Death occurred twenty minutes after the first convulsion. At the autopsy the brain and lungs were found congested, the right side of the heart was empty, and the left filled with clots of blood. In this case the susceptibility of the patient was obviously aggravated by the large dose injected into the rapidly absorbing mucous membrane. An unrecorded case of a fatal issue from the injection of cocain into the urethral canal occurred in this city about three years ago. Of five cases of cocain poisoning reported by R. W. Haynes of Los Angeles, Cal.,[15] two had a fatal issue. One of the latter cases was due to the injection of a solution of cocain into the urethra of a child to facilitate the passage of a sound. In an article on cocain poisoning by J. B. Mattison[16] four fatal cases of recent date are referred to, all following the use of a 4-per-cent. solution of the drug. Two of these were also urethral cases, the dose in one being 1 grain, and in the other $\frac{1}{3}$ of a grain. In the third case a 4-per-cent. solution was applied to a blistered surface, and in the fourth, a rectal case, $\frac{2}{3}$ of a grain in two doses, with an interval of ten minutes, was used. In the third case the symptoms were excitement, convulsions, and death, all within one minute.

Rhinolaryngologic literature has not furnished its quota of the reports of fatal issues from the use of cocain. Whether this is due to modesty or to the fact that the application of the drug in the upper respiratory passages may be more accurately controlled, it is difficult to state. The enormous extent to which cocain has been used, and the fact that fatal issues from other causes have been reported as faithfully in this branch of medicine, would favor the latter explanation of the lack of mortality from cocain in this region. Dentistry has not been so well favored in this respect, this being due to the fact that the gingival membrane has only a limited power of absorption, and the anesthetic effect of cocain is usually obtained by the injection of the drug. A fatal case is reported in the *Zeitschrift f. Zahnheilkunde*, Berlin, September 25, 1890. The patient, a woman aged twenty-nine years, was apparently healthy but quite nervous. The extraction of a tooth was painless and nothing abnormal was noted. The operator withdrew from the chair to obtain some water for the patient and on his return found her motionless. Physicians were summoned and artificial respiration practised, but without success. The quantity of cocain injected was $\frac{1}{3}$ of a grain. A useful moral in this case is that, if the dentist is not capable of treating a case of cocain

poisoning he should not administer the drug except in the presence of a competent physician.

In one case reported by R. W. Haynes,[16] death occurred from the injection of a solution of 4 grains of the drug into the gums for the extraction of a tooth. In addition to these fatal results, the records of dentistry show many cases in which the toxic effects of cocain have been exhibited without, however, being followed by a fatal result. Grassmann,[17] reports a case which is remarkable for the fact that the solution was not injected but simply applied to the gums, the effects developing after five minutes, when no more than ¾ of a grain had been absorbed. L. H. Broughton[18] reports a case in which 3 minims of a 20-per-cent. solution were placed in the cavity of a tooth, the application being followed by irregular and slow respiration, retarded pulse, and total unconsciousness. The patient recovered under the use of strychnin, which the author believes to be antidotal for cocain poisoning. In a case reported by Von Isoo[19] 1¼ grains were injected into the gums of a man of strong physique. The toxic symptoms which developed were of a severe character, palpitation, vertigo, and syncope, the effects not disappearing for several days. George Bock[20] reports a case of unconsciousness, blindness, and other toxic symptoms which followed the submucous injection of cocain into the gums.

Experiments on animals have shown that, in acute poisoning, the mode of death is that of asphyxiation, this being corroborated both by observation of the animals during life and by *post-mortem* examination of the bodies. An interesting observation shown by these investigations[21] is the effect of cocain upon the bodily temperature. The majority of experimenters who have tried this drug find that when injected intravenously into the jugular vein of dogs it produces a marked rise of the bodily heat. Langlois and Richet[22] also found that the variation of this bodily temperature by artificial means specially influences the power of the drug over the nervous system, and that animals whose temperature is raised by a warm bath before the dose is given rapidly become convulsed and die, the increased temperature of the body by the drug over and above that already produced artificially aiding in the production of a fatal issue. They have noted that cooling of the body prevents such a termination. These authors[23] have also shown that the convulsions following the injection of cocain into the animal economy are identical with those of cortical epilepsy, and claim that it is in all probability true, as a result of the discovery, that stimulation of the motor region of the cortex produces more marked effects than ordinarily occur under such circumstances.

While a close investigation of otolaryngologic literature has failed to furnish me with an instance of a fatal issue from the use of cocain, reports of the toxic symptoms are by no means rare, and, judging from the extensive—I had almost said reckless—manner in which this drug has been used this occurrence must have been by no means infrequent. A number of authors have called attention to the toxic effects of cocain, among whom may be mentioned H. Richards, D. B. Delavan, J. W. Gleitsmann,[24] and R. O. Cotter.[25] McN. Whistler[26] has twice seen vertigo and threatening syncope after applying to the nasal cavities a solution of cocain stronger than 4 per cent., but Schellenberg of Wiesbaden[27] reports the case of a patient in whom a 2-per-cent. solution of cocain, used in the nasal cavities previous to cauterization, was sufficient to develop severe toxic symptoms.

It would be well to state in this connection that too much importance should not be attached to the strength only of the solution, the principal item being the amount of the alkaloid employed. The application of a 5-per-cent. solution is not necessarily less dangerous than one of 20 per-cent. strength unless the amount used is specified. One dram of the former would contain 3 grains of the drug, whereas 5 minims of the latter contains but 1 grain, which would be less likely to develop toxic symptoms than the former. This point is emphasized for the reason that surprise is frequently expressed at the dangerous effects produced by a weak solution, the quantity of the solution used not being taken into consideration. A case of serious collapse from the use of cocain after an operation on an accessory cavity is reported by Baden of Denmark,[28] and F. Fox[29] gives an instance in which spraying of the throat for fifteen minutes with a 2-per-cent. solution of cocain produced weakness of the lower limbs, staggering, depression, and finally unconsciousness lasting for several hours. The amount of cocain that could have been absorbed by even this weak solution, when continued for fifteen minutes, is quite sufficient to explain the toxic effects produced. The application of a 4-per-cent. solution in a case of glossitis, which was followed by the most threatening symptoms, is reported by W. Richert.[30] Recovery took place under restoratives, but a second application produced the same effects. Gourand[31] refers to a case in which a 4-per-cent. solution was applied to the tonsil of a young man, and Fischer of Saaz[32] reports the case of an actor suffering from chronic pharyngitis in which the application of a 4½-per-cent. solution was used, both being followed by violent toxic symptoms.

In this regard it would be proper to state that the toxic effects of cocain in the pharyngeal or oral cav-

ities do not develop as readily from simple applications as in the mucous membrane of the nostrils, owing to the far greater power of absorption of the Schneiderian membrane. This is so rapid that cocain symptoms may be produced from its simple local application almost as quickly as when injected hypodermatically into other parts of the body. The pharynx and tongue possess this absorbability to a much less degree, and the application requires more perseverence, not only on account of the lack of absorption, but also owing to the fact that the solution is quickly diluted by the saliva which is secreted. A somewhat remarkable case is reported by Castex,[33] in which the application of a 20-per-cent. solution of cocain to the nostril was followed by severe local symptoms, the patient two days later ejecting from the naris a membrane analogous to one formed in fibrinous rhinitis. This circumstance might have been considered only in the light of a coincidence had not a previous application of cocain produced a similar result.

A number of substitutes for cocain have recently been suggested, such as eucain "A" and "B," holocain, etc., the advantage claimed for each of these drugs being its less toxic character. The limits of this article will not permit me to discuss the relative merits of these drugs. They have not come into general use and have not been applied in a sufficiently large number of cases to enable one to form a just valuation of their merits. This circumstance alone should be sufficient to prevent one from speaking too strongly of the absence of danger in using them, as recently has been done on several occasions. The method of Schleich in applying cocain is an important modification and is now very extensively used. The small amount of the drug in the formulæ of this method minimizes its toxic effects and it should be given the preference whenever applicable.

In addition to the toxic symptoms which may arise from the application of cocain one must consider a more remote effect but one which is far-spread in its evil and which now offers a serious menace to society. I refer to the development of the cocain habit. I regret to state that this habit follows more frequently from its application in the nose and throat than in any other branch of medicine, and in the majority of cases it results from the ill-advised prescription of the physician. In acute coryza in which it is so often used cocain temporarily relieves the turgescence of the tissues, the sneezing, and the irritability, and when once this dangerous agent has been placed in the hands of the patient, it is frequently a *facilis descensus*. The patient who applies this drug, and frequently the physician who prescribes it, little realizes that this beneficial effect is soon followed by dilatation of the cavernous tissue, due to paralysis of the vasomotor nerves, and that its continued use causes chronic congestion of the tissues which requires the cocain to be applied more and more frequently until even this remedy fails. That this effect frequently develops is shown not only by medical literature but also by the fact that many physicians use this as a routine measure not only for their patients but even for themselves. Hay-fever is another pathologic condition which encourages the abuse of this drug, and it frequently lays the foundation of a chronic nervous affection of the patient. A number of such cases have come under my observation and many have been recorded. It is to be regretted that the application of cocain in these affections has been recommended, and even in text-books on rhinolaryngology. Thus I find a well-known author who recommends a 4-per-cent. solution of cocain in acute rhinitis and acute pharyngitis, and another, an aurist, who recommends a 10-per-cent. cocain spray (!) in acute coryza.

The development of the cocain habit in this manner is an easy process, and the results are not only as dangerous as those of the morphin habit but are claimed by some to be even more rapid. Among these effects is a rapidly developing marasmus characteristic of this form of intoxication. The psychologic symptoms are quite marked, consisting of apprehension, delusions, and hallucinations, which sometimes resemble those developing in chronic alcoholism. There is insomnia, loss of appetite, and frequently complete impotence. The severity of these symptoms indicates that the substitution of cocain for the morphin habit is an exchange of no benefit to the patient, and the withdrawal of the former is sometimes followed by more severe reaction than in chronic morphinism. Among those who have called attention to the evil effects of cocain in this particular are Lennox Browne,[34] J. W. Stickler,[35] J. H. Woodward,[36] Seifort,[37] Obersteiner,[38] and Loewenberg.[39] The latter records two cases of young women who suffered from serious toxic symptoms, as insomnia, visual and auditory hallucination, attacks of mania and melancholia, anorexia, and gastralgic pains. The origin of the habit was the use of a snuff powder which contained cocain. Instead of using three or four pinches per day these patients took the powder in its entirety, the writer estimating that 1½ grams (23 grains) were used daily. In a case reported by A. P. Luff,[40] the patient used a 5-per-cent. solution of cocain in the nostrils on account of attacks of coryza. The remedy was found to be so pleasant that the patient became

addicted to its use and continued it for three years. At this time he was completely unfit for work and suffered from dyspepsia, chronic constipation, and palpitation. A similar case is reported by Finkelnburg,[41] in which a woman developed the cocain habit from using a snuff consisting of cocain and starch (5 to 100). The symptoms present were excitability, absent-mindedness, insomnia, hallucinations, dilatation of the pupils, and a disposition to cardialgia. An interesting case is reported by Maurel[42] in which a lawyer became a slave to cocain inhalations, this having been prescribed three years before for persistent asthma. The faculties had apparently become heightened and more headwork was done, but symptoms of brain degeneration, with unsteadiness of purpose and will-paresis had developed, the patient all the while believing himself to be improved.

Physicians, who suffer so frequently from chronic morphinism, are not exempt in regard to the cocain habit. The same facility of its use which is so often responsible for the development of the morphin habit also applies here, and unless the evil effects of the use of this drug are fully understood the number of cocain habitués will soon be greater than those suffering from morphinism. Two cases in physicians are reported by Zenner,[43] one of whom suffered from the cocain habit alone and the other from mixed morphin and cocain. In the first case the object of the cocain was to relieve fatigue due to work, but the physician soon developed an irresistible craving for the drug and abandoned himself entirely to its toxic influence. He lost his practice, squandered his property, and was brought to the brink of ruin. After four attempts at abstinence within two years he finally succeeded but still remains an attendant at the asylum where he was treated. In the second case cocain was used as a substitute for morphin. The delusions and hallucinations characteristic of cocain delirium developed to a marked extent in this case. At one period the patient used 60 grains of cocain hypodermatically per day. Ineffectual attempts had been made to discontinue its use but he finally died from tetanus after injury from stepping on a fork. A case of mixed addiction—morphin and cocain—is also reported by Laury,[44] the habit for the latter drug having been acquired by its use as a substitute for the former. The effects were of the most disastrous character, and Laury regards cocain as a toxic agent far more formidable than morphin on account of the rapidity and intensity with which the sensory, motor, and intellectual derangements develop under its use.

Investigations on animals have shown that in chronic cases of cocain intoxication there is a marked hyperemic condition of the central nervous system which presents a contrast to the other organs which are anemic.[21] Albuminoid degeneration is especially marked in the ganglionic cells of the spinal cord and the nerve-cells of the heart ganglia; it is present also, but to a less marked degree, in the muscular fibers of the heart, in the ganglionic cells of the medulla oblongata, and in the hepatic cells. In these last three is found an accumulation of glycogen. In chronic poisoning the degenerative processes are found to have advanced further in the cells of the spinal cord and medulla, minute cavities, atrophy, and hyalin degeneration being noted. In the heart there is fatty degeneration of the muscular tissue; in its nerve ganglia there is fatty degeneration, minute cavities and simple atrophy; and in the liver, atrophy of the hepatic cells is present. The vascular system is most affected in the spinal cord, there being cellular proliferation and hyalin degeneration of the coats. In the heart and liver an atrophic condition of the tissues is found, also a swelling of the endothelium of the capillaries of the cardiac ganglia.

In the majority of cases in which the cocain habit is established a prescription of the physician is responsible for the evils which result. When such a remedy is placed in the hands of a patient for an ordinary coryza, hay-fever, and many other conditions in which there is transient or only apparent benefit from its use, the habit is easily contracted, and many druggists, unfortunately, are prepared to supply all of the deadly drug that the patient may demand. In view of these considerations, the rule has a substantial foundation that cocain should never, under any circumstances, be prescribed for the patient's use, and above all, for the nasal cavities, where the application is made with such facility and from which many of the most severe cases have resulted.

A pecular phase of the cocain habit which has developed in New Orleans and in a number of other cities in the South is the contraction of this habit by the negroes. The extent to which this has spread can be easily verified by druggists and in police circles. It is not used in the manner generally prescribed, but a few crystals of the drug are snuffed into the nostrils, not on account of its contractile effects on the nasal mucosa, as is usually the origin of this habit in the Caucasian, as the nasal passages of the negro are normally quite patulous, but on account of its exhilarating effects. The physical and mental wrecks which soon result from this vicious habit attest to its pernicious effects.

While admitting the danger and evil results of the abuse of this drug, we should not, on the other hand, go to the extreme in condemning it in its

entirety, as has recently been done on several occasions. That this should be the case, however, is not unnatural, being the return swing of the pendulum of the early enthusiasm with regard to it. What is needed is that one should have a proper realization not only of the benefit but also of the danger of its application. The medical profession should be made thoroughly acquainted with the complications which may arise from the use of cocain, and the evil of placing such an agent in the hands of a patient. The druggist should be compelled to restrict the sale of this as well as of other toxic drugs to the prescription of the physician. As stated before, however, cocain should never be placed in the hands of the patient under any circumstances, as the habit is so easily acquired. In this manner we may retain the use of a valuable drug, and, by exercising proper care, eliminate its evil effects.

ACUTE DELIRIUM.[1]

BY H. R. COSTON, M.D.,
OF FAYETTEVILLE, TENN.

THE causes of acute delirium are not very well understood. Laverand reports a fatal case produced by a spiritualistic *séance*,[2] Spatling, a case from overwork,[3] and Potts[4] reports finding the pneumococcus in the fluids from a case of the disease. This was probably a mere coincidence, or possibly sufficient care was not taken to sterilize the instruments used in making the bacteriologic examination. Prout[5] reports a case with *ante-mortem* thrombi in the circle of Willis; but these were possibly a result rather than a cause of the disease. The most extensive article I have seen dealing with this subject is that of Dr. H. C. Wood in the *American Journal of the Medical Sciences*, April, 1895. Dr. Abbott made the bacteriologic examination in a case reported therein and his report is as follows: "I have not succeeded in finding *anything* either by microscopic or culture methods in the material taken from the meninges of your case on Saturday."

Acute delirium may follow or develop during other diseases. Potts relates a case, fatal the third day, following carbuncle of the upper lip. It may also arise, seemingly, *de novo*, for often one is unable to find any causative agent. Both sexes are alike liable to it. It is a disease of adult life, both extremes of life being partially exempt. From fourteen to forty-five years is the age most liable to the disease. More cases occur under thirty than afterward. I believe it to be a toxemia expending its force upon the cortex cerebri. It possibly is an auto-intoxication due to deficient elimination, or to the absorption of waste materials which should be thrown off by the emunctories, or to overwork, either mental or physical. Kraft-Ebing thinks the disease due to hyperemia with irritation, and, as a consequence, exudation, which causes pressure on the nerve-cells. In the latter stages this exudation amounts in quantity to an edema, but this hyperemia and exudation are results rather than causes. Heredity plays no part in its production.

[5] MEDICAL NEWS, August 18, 1894.

The disease usually begins very suddenly and the first impression made by the patient on his family and friends is that he has "gone crazy." Occasionally the attack is preceded for a few days by distinct prodromic evidences of cerebral disturbance. I have had three cases under my care and in each of them the onset was very sudden.

Case I.—Female, aged fifteen years; seen in consultation with Dr. Hatcher of Hazlegreen, Ala. Previous history good; mother died in childbirth; father and one sister living and healthy. No history of insanity or other cerebral troubles on either side of the family. A paternal cousin is an epileptic. The patient menstruated at twelve and has been regular ever since; period then due. She was of excellent family and had always been very modest and extremely chaste in her language.

Dr. Hatcher was called to her in the early part of the night of October 24, 1893. She was very restless and slightly delirious, using uncouth language, complaining bitterly of pain in her head, also somewhat of pain in her hips and back. There was great motor excitability, the patient desiring to be in constant motion, and occasionally cursing and abusing those about her. He gave morphin hypodermically, and bromid internally. She steadily grew worse, and at dusk, October 25th, I saw her. She was sitting up before the fire talking rapidly and swearing with almost every breath all the oaths in the vocabulary. No words were too foul to pass her lips. She recognized every one and spoke to me, calling me by name, although it had been three years since I had seen her. When I offered to place the thermometer under her tongue she cursed me and said she did not want that nasty thing in her mouth and placed it in the axilla. Her temperature was 101° F.; pulse, 100. The pupils were about normal — possibly slightly contracted. Sense of hearing was extremely acute. After one had talked with her a few minutes and left her for a short time she would speak to him as if she had not seen him for days. having no recollection that the visitor had left her only a few minutes before. Although she knew everybody she could not talk rationally. There was absolute anorexia, but no nausea or vomiting. The bowels were constipated and action of kidneys sluggish, but the urine was normal. She did not try to fight the attendants but tried to destroy everything she could get her hands on. As she was growing worse we stopped the morphin and gave her 30 grains of chloral. As a result, she slept five hours but awoke worse than ever. She jumped out of bed, caught up a guitar and played a bar or two and then smashed the instrument over a chair and cursed violently. I gave her another dose of chloral, 15 grains, but this did not produce much sleep but kept her quiet and dozing for several hours. I had given her calomel and aloes and in the morning a good action of the bowels was secured. She continued to grow worse. Sulfonal, trional, paraldehyd, etc., were tried, but hyoscin hydrobromate in large doses gave the best results; after taking $\frac{1}{200}$ of a grain she would sleep from six to eight hours. She died on the thirteenth day from exhaustion. She was never rational, but for five or six days before she died the delirium was more of a typhoidal type and the physical excitement was not nearly so great; indeed, it was almost absent because of the complete prostration. The highest temperature was 102° F., the lowest 100.5° F. The bowels were constipated all the time. For several days before she died she was apparently blind, the pupils being widely dilated.

It is of importance to carefully watch the temperature in these cases, both for diagnostic and prognostic reasons. It very seldom rises above 103° F., or falls below 100.5° F. Patients usually live from ten to fifteen days, though they may die in three or four days, as illustrated by the following:

Case II.—Female, aged thirteen years. Family history good; no consumption; no insanity; no epilepsy or other cerebral disorders; no drunkenness; parents and large family of brothers and sisters living and healthy. Had never menstruated and signs of puberty just beginning to appear. Temperature in axilla 100.5° F.; pulse, 110. The patient was very delirious, cursing, blackguarding, rolling and screaming. She complained bitterly of headache. Pupils slightly dilated, but reacted to light. Bowels costive; no nausea or vomiting. I at first thought this was a case of hysteria, but soon discovered my mistake. She died suddenly at the beginning of the fifth day while sitting over the commode.

The great physical excitement deserves careful attention, as in no other disease have I ever seen such universal and constant motion. The rapidity of exhaustion is remarkable. A robust person weighing 150 pounds will rapidly lose 50 pounds. The urine is usually diminished in quantity and often has to be withdrawn by a catheter. Vision is weakened and may be lost entirely for several days and then recovered, as will be shown to have occurred in one of my cases. I believe that in fatal cases blindness usually occurs before death, but I cannot be positive on this point. The sense of hearing is extremely acute, the patient starting at the least noise, declaring devils are about her. The sense of smell in one of my cases was increased very considerably. All the patients I have seen have had delusions of some kind. The sense of touch may be normal at first but later becomes benumbed. If sitting on a chair or bedside the feet and legs are moving as if trotting a baby on the knees. The arms and hands are in constant motion as if washing dishes, churning, or working a pump-handle, while the muscles of the trunk sway the body back and forth or into various positions. The third and last of my cases brings out many of the above points.

Case III.—Female, aged twenty years; seen in consultation with Dr. Jean of Lincoln, Tenn. Sin-

gle, robust young woman, weighing 145 pounds. Menstruated at twelve, but had never been regular. Early in menstrual life the menses would appear every two weeks; later they would sometimes miss five or six months. She was a stout country girl, raised to work, milk, cook, churn, or do the family washing, as the case demanded.

Family history perfect. The patient had had typhoid fever four years previously, and measles when a child. She was taken when at church Sunday with what was thought to be a chill, but the slight fever was not sweated off, and the delirium was out of proportion to the amount of temperature.

I was called the following Tuesday, August 13, 1895. So much did the shaking and general physical excitement resemble a chill that the messenger stated that the patient had a chill and they thought it was of the congestive type as she was still shaking, not having gotten entirely over the Sunday shake. The muscular tremor, pain, and delirium were not so marked Monday as they were then or had been on Sunday. I reached her at 2 P.M. She was sitting on the edge of the bed and it seemed that every muscle in her body was in rapid motion. She recognized me and asked that I do something for her and then drifted into all kinds of foolish talk. Dr. Jean was giving her a hypodermic of morphin when I went in. After a few minutes she was more quiet physically.

My first impression was that we had to deal with an aggravated case of hysteria, and so expressed myself, but when I had an opportunity to make a careful examination I found the pulse 100, the temperature 101° F., pupils slightly contracted, bowels constipated, action of the kidneys limited, skin dry, anorexia, no nausea, no vomiting, and, of more importance than any other single symptom, that she did not remember that I had been with her only a few moments before. The delirium, while constant, was not of that vile, profane, uncouth nature of the two preceding cases. She would talk of her menses in one breath, of her sweetheart in another, and then of the ailments of some one else, in a few moments talking of a dozen different things. Her hearing was extremely acute and the least noise would cause her to scream for protection. The sense of smell was also unusually acute. If I had been smoking she would quarrel with me about it as soon as I came in. Her body was in constant motion, being thrown in all directions, the feet and legs going all the time, making it difficult to keep the bedcovers on her. She would roll from one side of the bed to the other and then back almost constantly. Morphin would quiet the muscular tremor somewhat, but had no effect on the delirium, unless it was to make it worse. Heart and lungs were normal. There was considerabie tenderness of the left ovary.

She lost flesh very rapidly and would, I think, at the end of ten days, not have weighed more than 100 or 110 pounds. We discontinued the use of morphin and gave her fluid extract of ergot, bromid of potash, and chloral hydrate, and during the night gave hydrobromate of hyoscin, gaging the dose by the effect, but never giving less than $\frac{1}{100}$ of a grain, and often three times that quantity. We used sulfonal, trional, duboisin, etc., but nothing gave the good results obtained from the hyoscin. At the end of a week, when the physical excitement had abated, we gave her strychnin and digitalin. We also employed enemata or cathartics to unload the bowels when necessary. Her temperature varied from 100° to 103° F., but was usually about 101° F. Her pulse varied from 100 to 135 or 150. About the tenth day of the disease it was found that she was totally blind, though the sense of hearing and smelling was very acute. At this time the physical symptoms were at their worst, and then began to improve gradually. The blindness lasted four days, and then sight slowly returned, but two weeks later she was unable to see the hands of a watch.

The mental symptoms began to improve a week after improvement was first noted in the physical symptoms. When the physical symptoms began to improve the appetite returned and she rapidly gained flesh and strength. Two weeks after I had ceased my visits she had a slight relapse, but being sick myself at the time I did not see her; Dr. Jean and the family tell me it was nothing to compare with the first attack. I saw her a few days ago—two years after recovery—and she seems in perfect health mentally, and weighs 150 pounds, but under excitement there is yet some jerking of the muscles, especially the right hand and arm. She has no recollection of my seeing her while she was sick.

Let us examine the points of interest in these three cases: Concerning the cause of the first two I am unable to arrive at any conclusion; the third was probably caused by worry on account of the non-appearance of the menses. All of the patients were constipated; all had great motor excitement; all were delirious; all had fever—100° to 103° F.; all had rapid pulse—100 to 130 or more; in two the pupils were slightly contracted at first, but all were dilated later on; in one blindness occurred which lasted four days, and I believe the two who died were blind before death occurred, or that the vision was extremely dim; all had severe headache; in all the sense of hearing was increased; in one the sense of smell was also increased, which was probably true of the other two but was not noticed; tactile sensibility was normal or slightly increased in all at the beginning, but after a few days it was diminished; all had insomnia; in all the action of the kidneys was diminished, but this was probably due to the limited amount of water taken into the system; in all the action of the bladder was weakened and occasionally required the use of the catheter; all rapidly lost flesh; all could recognize the doctor but could not talk rationally; in no case was there nausea or vomiting; no paralysis; and in the patient who recovered there was no memory of anything that occurred during her illness.

The first patient died in two weeks; the second died in four days, and the third was beginning to improve at the end of two weeks.

The symptoms, in a few words, are: Elevation of temperature, rapid pulse, absolute insomnia, acute hearing, dimness of vision, wild hallucinations, outbreaks of great violence, and great profanity and vulgarity from the most refined and gentle of girls. The patient sees devils, scorpions, lizards, and rats; tears her hair; beats herself or the wall with her hands; throws her feet in the air; destroys anything she can get her hands on, but shows no disposition to fight; great motor excitement; the ability to recognize friends and inability to talk rationally; forgets in a few moments that she has seen you. At the end of a week or ten days she gradually passes into a typhoid condition and dies within fifteen days in coma. Death may occur in from three to five days, in which case it occurs during a paroxysm.

I can readily see how a case of acute delirium could be mistaken for one of typhoid fever if not seen until exhaustion has set in, unless one is careful to obtain a thorough history of the case. Folsom[1] says typhoid patients are sometimes sent to the asylum as cases of acute delirium. The regular rise of temperature, the eruption, the diarrhea, all make the diagnosis of typhoid easy, and if doubt remains, the bacillus of typhoid may be found.

Acute delirium may be mistaken for hysteria for a short time, but the clinical differences are so marked that the mistake will soon be corrected. The hysterical patient may not emaciate, she may have retention of urine, but the secretion is abundant; she will not have the temperature so constantly elevated; one will detect the hysterical patient at every point making use of all means to gain sympathy, but the patient with acute delirium neither desires nor tolerates it. Hysterical patients are not usually profane or vulgar.

Acute delirium and acute mania are more frequently mistaken for each other, and the differential diagnosis is more difficult to make, but with care it may be done. The symptoms of acute delirium are much graver, the course briefer and more definite, and the temperature is elevated in acute delirium and lowered in mania. The exhaustion is very rapid in acute delirium while the maniac will continue to rave for months with little perceptible loss of strength. Mania is a conscious delirium, the patient being aware of what he is doing and taking every advantage of his attendants. Acute delirium is an unconscious delirium, the patient never trying to take any advantage, and, although he recognizes those about him at the time, five minutes later he does not remember to have spoken to them. In mania the appetite is usually enormous, while in acute delirium it is always absent. Mania is preceded by marked prodromata, while the prodromata of acute delirium are never marked and often absent. In mania the face is often flushed and the sclerotics injected; in acute delirium it is pallid and there is no injection of the sclerotics. Acute delirium terminates in death or recovery in two or three weeks, while mania usually persists for months.

Wood, in the paper already referred to, sums up thus: "The symptomatic differences between acute delirium and acute mania are found in the suddenness of the onset of acute delirium, in the rapidity of development of typhoid symptoms, and especially in the presence of a pronounced febrile reaction." Kraft-Ebing is quoted as saying that if in any case of mania the temperature rises to 105° F. it strongly indicates the presence of acute delirium; but it should be remembered that any inflammatory complication will cause a rise of temperature.

The pathology of acute delirium is little understood. I regret that in neither of my fatal cases was I allowed to make an autopsy. There is hyperemia of the cortex and membranes, which is rapidly followed by edema and choking up of the lymph-spaces with blood-corpuscles. Minute hemorrhagic foci are found in the cortical substance and there may be diminished consistence of the brain.

Dr. Guiteras reported as follows on Dr. Wood's case, previously referred to: "No gross lesion was apparent except that the membranes were congested, but not opaque. . . . Fresh sections into the brain substance showed well-marked congestion. . . . The inflammation process affects the blood-vessels, the lymph-channels, and the connective tissue. . . . There is nowhere to be found in these tissues any tendency to liquefaction or suppuration. . . . No bacteria or other abnormal contents are found in the blood-vessels. . . . Ganglion cells and protoplasm show no structural change. . . . No evidence of degeneration of the myelin." Certain it is we do not really know what the pathology is, for the changes found are insufficient to account for the symptoms present. My opinion is that the cause of death is the impression made on the cortical cells by a microbe, or the ptomains produced by a microbe, though what these changes are we do not know.

Comparatively little has been written concerning the treatment of this disease. Osler says he would not hesitate to bleed freely, but I think we should select our cases in which to employ this measure. In fulminant cases, such as Case II., above reported, I believe bleeding would be of service and

[1] Pepper's "System of Medicine," vol. v.

regret that I did not employ it, but owing to the extreme rapidity of exhaustion one should avoid all measures calculated to depress the patient. If bleeding is resorted to at all it should be in the very beginning of the disease. Cold may be applied to the head with good results. The bowels should be well emptied by the use of calomel. Ergot may be given for its effects on the blood-vessels, but I have little faith in it; if used, it is best given hypodermically. Bromid and chloral may be given freely. Paraldehyd caused quiet sleep in one of my cases, but it has to be given by the mouth and is therefore not so useful as drugs which may be given under the skin. Duboisin has many friends, but in my hands it has failed to come up to its recommendations. Sulfonal and trional are useful, but owing to their limited solubility in water are inconvenient to administer. Trional is by far the preferable drug of the two. Morphin alone is positively harmful, but may be given advantageously combined with hyoscin. Hydrobromate of hyoscin, in doses of from $\frac{1}{60}$ to $\frac{1}{20}$ of a grain, far exceeds all other remedies that I have ever used in any form of insanity. It must be given freely. I have never seen any bad results from its use, and in a case of acute melancholia with absolute insomnia of a week's duration, which I had the pleasure of seeing in consultation with Dr. Davis, in which morphin and the bromids had absolutely no effect, I gave $\frac{1}{10}$ of a grain of the drug at a single dose, and the girl was asleep in two minutes and slept eleven hours. She made a good recovery. After a large dose the patient will gasp a few times and if one is not well acquainted with the action of the drug—not from reading alone, but from bedside observation— one will fear that immediate dissolution is impending. If the patient is left alone she will be all right, but administer restoratives and the like and she will be very apt to die. When exhaustion has set in strychnin should be given in oft-repeated doses. The heart should be supported with digitalin.

During the entire course of the disease an effort should be made to nourish the patient with liquid food. When the crisis is reached stimulants should be given in the form of egg-nog. The room must be kept absolutely quiet from the beginning of the attack and more than two persons should never be permitted to remain in the room at once. The bladder should be emptied regularly with the catheter and the bowels opened daily with enemata.

Dr. Senn Resigns His Position in the Army.—At his own request Lieutenant-Colonel Nicholas Senn, Chief Surgeon of Volunteers, was honorably discharged from the service of the United States September 21st. Dr. Senn has returned to Chicago to resume his professional work.

THE VALUE OF ELECTRICITY IN GYNECOLOGY.[1]

BY W. E. FORD, M.D.,
OF UTICA, N. Y.

THE usefulness of any therapeutic agent or of any single surgical procedure is not determined so much by the enthusiastic advocates who are especially skilled in the matter, as upon the evidence of the average practitioners who are doing the great bulk of medical and surgical work in the world. An agent that is even fairly successful in the hands of the great majority of educated physicians cannot be justly condemned because there are experts in the same field who secure more brilliant results by other means. Sober-minded people are not very much impressed by the enthusiastic utterances of those who claim to secure marvelous results by any single therapeutic agent, but the fact that enthusiastic writers claim altogether too much for any new method or agent should not wholly condemn it. Time alone settles the question of usefulness of any therapeutic agent or procedure. The prejudice which to this day exists regarding electricity in gynecology or in any other branch of medicine or surgery, is not altogether unjustifiable. In some form or other it has been used for so long a time, and the fact that its influence is mysterious, has kept it before the mind of the profession as long as medical records have been kept.

The earlier experimenters who announced astonishing results from the use of electricity in sickness were rarely scientific men, and very frequently were not physicians at all; and even down to the last decade electricity has principally been used by quacks. External therapeutic agents received very little intelligent attention from medical men during all those years when drugs were given in heroic doses. Massage, and the various forms of baths, when I was a student, were looked upon with very little favor by the so-called regular profession. But calomel has not ceased to be a useful agent simply because it is no longer given in the heroic doses of the olden times. Massage has come to occupy a useful and dignified place alongside of various kinds of baths in the treatment of different disorders.

It was unfortunate for electricity that its revival upon a scientific basis, with the introduction of instruments of precision which not only regulate the quantity of electricity to be used but also enable us to record the results in scientific terms and thus show what it really can do, came with such enthusiastic and vociferous claims as to its universal efficacy on

[1] Read at the Twenty-third Annual Meeting of the American Gynecological Society, Boston, May 24, 25, and 26, 1898, in discussion of the topic: "Has Electricity Ceased to Be a Useful Therapeutic Agent in Gynecology?"

the part of the few men. Modern surgical gynecology was developed at about the same time and gave such brilliant results that more conservative measures were ridiculed by many who would acknowledge nothing but the knife as the savior of womankind. In exactly the same way hypnotism, which was making really wonderful advances, was relegated to obscurity by the discovery of ether and chloroform. There is no doubt that electricity would have held the first rank as a useful agent in gynecology, even in the treatment of fibroid tumors of the uterus, had not aseptic surgery reduced the mortality of abdominal operations to such an astonishing degree within the past few years. It is as unfair as it is unwise at this time to say that all therapeutic agents are useless which do the work that may be more brilliantly done by surgical procedure in the hands of a few expert operators. It is not true that operative work which is so successful and so brilliant in the hands of a few is safe or even justifiable in the hands of the many; but lesser procedures, not involving the same risks and accomplishing satisfactory results in perhaps a slower and more tedious way, must and ought still to be recognized and advocated for the relief of minor ailments.

There are many things in gynecology which electricity does very much better than any other agent which we now know. Its field is limited and fairly well defined, and within these limits electricity may be used, not only with safety but with great advantage by us all. Perhaps there is no better way of stating this subject concisely than to mention certain conditions that are very markedly benefited by this agent, upon which all fair-minded operators of considerable experience would agree.

Cases of amenorrhea in young women, not dependent upon true anemia, but rather in connection with plethora, in which there is an undersized or undeveloped uterus due to perimetric inflammations which have resulted in slight bands of adhesions about the broad ligaments, cutting off the blood-supply, are not only very important as a class but they resist every method of treatment except that by galvanism. Again, amenorrhea following long, exhausting nervous affections with or without anemia, is in almost all instances relieved by faradism applied but a few times. This last class of cases is, of course, not so important as the former, but, nevertheless, after insanities and the graver nervous disorders, the tendency to relapse is much lessened by the early establishment of this function which usually has been suspended.

Simple metritis, where the ovaries and tubes are not infected, is successfully treated by galvanism, as is simple metritis due to subinvolution. Curetting and packing is more brilliant but not always a more certain method of relief; and owing to the fact that a single curettement is not always sufficient, a surgical procedure is not in all cases more speedy. Perimetric inflammations without the formation of pus, leaving exudates in the broad ligaments with more or less fixation of the uterus and ovaries, is as successfully treated by galvanism as by surgery. In these cases the amperage of the current must be large in order that the electrolysis may be secured. Collections of pus within the tubes or about the ovaries, or in pockets back of the uterus, always prohibit the use of galvanism.

Dysmenorrhea dependent upon a neuralgic tendency or upon the presence of slight bands of constriction about the Fallopian tubes, without pus formation, is more speedily and more permanently relieved by the intelligent use of galvanism than by any other means Obstructive dysmenorrhea, in which some of us have less faith than we used to have, is more speedily relieved by the slitting of the posterior lip of the cervix, thorough divulsion, curetting, and packing. It will be found, however, that these cases are not so numerous as those in which painful menstruation is due to the causes first mentioned. Even in these cases where there is a pin-hole os, and an undeveloped cervix with a flexure, galvanism brings about a cure in the majority of cases. The total amount of misery, disability, and attendant nervous disturbances produced by the conditions mentioned would seem to be almost as great as that produced by fibroid tumors and kindred grave affections. Of course, the mortality is less, but if unrelieved it is doubtful whether these simple cases may not develop into the most serious affections.

Up to this point I think no one will dispute the superiority of electricity over other agents and methods, if the physicians have been in the habit of seeing much gynecological work in private practice and have given electricity serious consideration. There are other disorders which can fairly be said to belong to surgical gynecology, but in which the patients refuse operative procedure and in which electricity used as a palliative or as a more slowly curative agent is decidedly useful. Hydrosalpinx is such an ailment which, though rare, I have repeatedly seen entirely relieved by galvanism. Subinvolution dependent upon an infection after childbirth, where there are no purulent collections about the tubes or ovaries, may be relieved and still allow the patient to pursue her ordinary avocation, a matter not to be treated lightly among working women. Small fibroid tumors embedded in the wall of the uterus, causing inconvenience by reason of weight and pressure, may

not only be successfully treated by galvanism, so that they lessen in size and become stationary for many years, but they may also be caused to entirely disappear in some instances. I have never yet seen a large fibroid tumor degenerate from the use of galvanism or become changed in any way so that it could not be operated upon as easily after the use of electricity. The charge that galvanism used with any degree of skill in cases of large fibroids renders them inoperable, is not based upon any known fact.

Some ten years ago, when hysterectomy was attended by a higher mortality, and when my own skill as an operator did not warrant me in removing large fibroids, in instances in which the patient refused to have a total extirpation by other more successful operators, I used galvanism in very large currents after Apostoli's method in a large number of cases. During the past five years I have advised the removal of fibroids by the knife, and now generally perform this operation in preference to any trial with galvanism. I have been surprised, however, within the past year to find a number of these cases of ten-years' standing in which there has been no increase in the size of the tumor, and little if any recurrence of pain, the subjects being able to work and refusing operation for total extirpation, even though the dangers are very slight. This in no case relates to bleeding fibroids, or to purely subserous growths.

In the clinic established at St. Luke's Hospital two years ago for working women only, I urged upon the attending physician the value of galvanism in the class of cases I have mentioned. He expressed strong objection to its use on the ground that previous experience in Philadelphia and Boston, where he had seen a large amount of the best surgical work of a gynecological nature done, had proved that it was not only useless but dangerous. I insisted, however, and now there is no more enthusiastic advocate of the use of electricity in the treatment of the minor gynecological disorders of the working classes than this physician.

I am firmly convinced, therefore, that electricity is useful in gynecology, that it will hold its place, and that many who have abandoned it for more brilliant operative procedures will resume its use. Those who are not giving their entire time to surgical gynecology, but who must care for the minor cases of this kind while also doing general medical and surgical work, will continue to testify to its usefulness.

Smallpox Quarantine against Mexico.—Notice has been given to the Mexican Central R. R. officials that no passenger is permitted to enter the United States unless he can show evidence of successful vaccination.

BICYCLE URETHRITIS.

By JOHN M. ROBINSON, M.D.,
OF DULUTH, MINN.;
PHYSICIAN TO ST. LUKE'S HOSPITAL.

FOR a time after the advent of the modern bicycle the male perineum, as a medical and surgical subject of discussion, bade fair to rival its analogue of gynecologic and obstetric fame. Lately we have heard less of the theoretical argument concerning the proper shape of bicycle saddles, and the alleged dangers to the sensitive organs involved in the fashionable straddle, yet it seems likely that in the average male rider the deep urethra, the prostate gland, and the base of the bladder are, indeed, subjected to a considerable degree of pressure and bumping; but whether, when these parts are perfectly healthy, any ordinary amount of this pommeling of the perineum can produce disease, I think exceedingly unlikely.

I have had under observation during the past three or four years several sore urethræ, and tender, swollen prostate glands, each case at first appearing to be due to the injurious pressure of a defective bicycle seat, but careful inquiry and examination have always revealed that there was still another cause for the prostatic or urethral inflammation.

CASE I.—A. W., a clergyman, aged about forty-five years came to me complaining of tenderness in the region of the prostate, and slight difficulty in urinating. These symptoms had come on gradually since he began to use a bicycle, two years before. He had an old-fashioned saddle, but was not in the habit of taking long rides.

On examination I found the prostate gland somewhat enlarged and quite sensitive to pressure. The urine contained a number of pus-cells and mucus shreds, but its more pronounced peculiarity was a high specific gravity and an abundance of urates and uric-acid crystals. The general health of the patient was fair, although he complained of occasional "rheumatic twinges" and "bilious headaches." Venereal disease was denied. The man was directed to lay aside his wheel; lithia water was ordered, and a regimen instituted suitable to his uric-acid tendency, whereupon all symptoms of the prostatic trouble abated, and in a few weeks the gland had recovered its normal condition. The following summer the gentleman again took to his wheel; he now used a saddle of the most approved pattern, and drank lithia water "to keep his urine clear," but in spite of these precautions the old soreness soon returned, and he was obliged to give up riding, this time for good.

CASE II.—A machinist, aged fifty years, consulted me for headache, backache, loss of appetite, etc. In the course of my examination I asked for a specimen of urine, and found that it contained a uric-acid sediment and also a number of pus shreds. I asked the patient if he had had gonorrhea. He

admitted but one attack, and that twenty-five years ago, but in the course of this inquiry he mentioned having had considerable soreness after riding his bicycle, and an occasional slight running from the urethra. The prostate gland was enlarged, and the posterior urethra was found to be somewhat inflamed. He was ordered to keep off the bicycle and was treated for a uric-acid accumulation. In a short time the urine cleared up and the urethral irritation disappeared.

Case III.—While I was treating the man above-mentioned, he spoke of two or three friends who were troubled in the same way—"were sore in the seat after riding and had a little discharge." He said he would send them around for an examination. A day or two later one of them came to see me. His urine was free from an excess of irritating material, but an attack of gonorrhea, three years before, explained, to my satisfaction, the mild urethritis which now followed every long ride on the wheel.

Case IV.—P. W., a young man much devoted to bicycling, in November last began to have a slight urethral discharge soon after having visited a brothel. This condition lasted not more than a week when all evidences of specific urethritis totally disappeared. Gonococci were not found in the pus which appeared at the meatus. During the following winter there were no signs of urethral inflammation, but about the middle of March, for the first time in four months, the man got out his wheel and took a twenty-mile run, and that evening he brought me a specimen of urine milky with pus-cells. He also complained of some soreness along the posterior urethra. Both of these symptoms disappeared after a few days' rest. I was inclined to hold the November attack responsible for the present trouble.

Case V.—During the summer of 1895 I treated a young man for a long-continued attack of specific urethritis. Finally the bothersome gleety stage came to an end, and for a year there was neither sign nor symptom of the urethral disease. At the end of this time he went to England, and while there commenced to ride a bicycle. Soon he noticed a little soreness along the urethra and had a little difficulty in "starting his water." These symptoms disappeared when he laid aside his bicycle for the winter, but again made their appearance when he began wheeling during the present summer. He came to me to find what the trouble was. His urine contained small pus shreds, which evidently came from the posterior urethra, and the prostate gland was found to be slightly enlarged. He has had to give up wheeling entirely for every ride brings on more of the old trouble.

Quite recently I was discussing this subject with a medical acquaintance, who had had under his care a patient suffering from a deep perineal abscess, which the doctor attributed to the continual use of a bicycle saddle of the most unhygienic and uncomfortable pattern. I mentioned my own experience in this matter, and the physician replied that his patient had had gonorrhea, but not in five years. To my mind this admission was highly significant in accounting for the bicycle abscess.

My brief experience thus leads me to believe that the inflammations of the deep perineal region, brought on by the use of the bicycle, have nearly always some secondary and underlying cause. Thousands of riders undergo this daily bumping, many of them mounted on rail-like saddles, and all without sign of damage. But the urethra, or the prostate gland, which still has lurking in its crypts and folds some relics of an old gonorrhea, or a mucous membrane irritated by uric acid I think are the conditions which the hard, humped-up bicycle seat is likely to stir into annoying activity. It would also seem to be very wise for men having any enlargement of the prostate to avoid the modern traveling machine.

CLINICAL MEMORANDA.

INTRALIGAMENTOUS FIBROID OF THE UTERUS WITH ADHESIONS TO THE OVARY; MYOMECTOMY.

By J. COPLIN STINSON, M.D.,
of San Francisco, Cal.

Mrs. W., aged thirty-five years. During 1894 she began to have a copious vaginal discharge, although since early childhood she had had a discharge, probably due to vulvovaginitis. In the fall of 1894 she received some form of electric treatment for her pelvic trouble. This was not attended by distress during the treatment, but afterward the pain was excruciating. Since then she had had pains in the pelvis and left side of the lower abdomen. In December, 1897, while lifting a bucket of water, she felt a peculiar pelvic pain which was dull in character and continued for several days. There was also constant pain in the left side. Examination at this time showed that there was milk in the breasts, and the uterus was somewhat enlarged. She continued to menstruate, but the flow had been and was peculiar for some time. She would pass a drop or two of blood during three days, and on the fourth she would begin to flow and the bleeding would always be quite severe and last usually five days; later she would pass clots of blood. She was examined March 13, 1898, by Dr. George Gross, but the abdominal muscles were so contracted that nothing could be made out with any degree of satisfaction. On March 17, 1898, she was examined under chloroform by Dr. Gross and myself. We found endometritis, and the uterus was somewhat enlarged, but in good position and movable. The left ovary was enlarged about three times the normal size, and was prolapsed and adherent. On the right side there was a mass the size of a hen's egg. It extended from the right uterine cornu and right side and posterior surface of the uterus outward into the pelvis.

On April 16, 1898, I operated, assisted by Drs. Gross and Burgess. Chloroform was administered by Dr. Putman, by the drop method. The patient was first placed in the lithotomy position, the cervix was dilated, and the uterus curetted and irrigated. The vagina was then tightly packed with plain gauze. This was done to push the uterus and adnexa as high as possible. The legs were then extended and a vertical incision about 2½ inches long was made above the pubes, dividing slightly to one side of the median line the skin, a thick layer of adipose tissue, the fascia, and the right rectus muscle. The peritoneum was opened at the upper angle of the incision and then torn down to the lower angle with the fingers. She was then placed in the Trendelenburg position, and the pelvis examined. The manipulations and the intra-abdominal work were made very easy by the pushing up of the uterus by the vaginal packing. This I think of value, and I intend to employ it right along in such cases. The fundus was readily located and brought to the surface. In the right cornu of the uterus was a fibroid tumor about the size of a hen's egg. It was firmly attached to the right cornu and the adjacent portion of the posterior surface and wall of the uterus. The Fallopian tube was displaced downward about half an inch, being located in front of the mass, which spread out into the folds of that portion of the broad liganient which contained the vascular supply of the right ovary. The external surface of the fibroid was rather firmly attached to the inner surface of the ovary, which was about 1¾ inches long. Its attachment to the mass was about 1¼ inches long.

The connections between the ovary and fibroid were separated by blunt dissection, aided at times by cuts with a scalpel. This necessitated division of the broad ligament for about 1¼ inches. The dissection was carried very close to the ovary. By this means no vessel was cut that required clamping. The cut edges of the ovary were at once sutured with fine chromicized catgut. This freeing of the ovary cut off about three-fourths of the blood supply. I concluded, rather than sacrifice any ovarian tissue, to trust to the remaining portion of its blood-supply to furnish nourishment for the whole organ. A circular incision was then made around the fibroid at its attachment to the uterus, an estimate first being made of the amount of uterine peritoneum that should be left so that the cut edges could be brought accurately together with sutures. The fibroid was freed and removed from the muscular wall of the uterus by blunt dissection, and the cut edges of muscular and peritoneal layers were united by continuous fine chromicised cutgut sutures. The left ovary was bound down by a few adhesions. These were separated and the ovary and the tube brought to the surface. The tube was patent. The ovary was about three times the normal size and contained several cysts, two of the size of a large hickory-nut, and another one-third this size. These were evacuated and then excised. The raw surfaces where the ovary had been adherent were also excised, and the cut edges of the ovary united with continuous sutures of fine catgut. This reduced the ovary to about one-third the normal size. The cul-de-sac was sponged out and the abdomen closed in separate layers with continuous sutures, of fine chromicized catgut for the peritoneum, chromicized tendon in two layers for the muscle and fascia, and very fine silk for the skin. The wound healed by primary union. The silk stitches were removed on the eighth day. The patient was allowed up and about in the third week, when she went without any bandage or support. She is now quite well. Examination shows the uterus and appendages to be in good position. She menstruated May 18 to 20, 1898, for the first time since the operation. She had no pain. The quantity and quality of the flow appeared normal. She has no pain or other symptoms referable to the abdomen or pelvis.

These favorable results show that conservative operations, or what I think would be better called scientific pelvo-abdominal surgery, should be more frequently employed as our patients can be cured without interference with the physiological actions and relations of their pelvic organs. I believe that when it is possible one should avoid removing any portion of ovarian tissue that appears normal, even though the portion of ovary remaining be small. Resection and plastic operations should be practised when pregnancy is liable to occur and delivery at term can be conducted with safety. An effort should always be made to cure our patients without depriving them of their menstrual function, as sometimes the symptoms which follow double oophorectomy or hysterectomy are more taxing than those which were present before the operation was performed. I report this case as it presents several points illustrative of conservative operations on both the uterus and appendages.

A CASE OF SYRINGOMYELIA.[1]

By THEODORE DILLER, M.D.,
OF PITTSBURG, PA.;
NEUROLOGIST TO THE ALLEGHENY GENERAL HOSPITAL.

C. A., an iron-worker, aged thirty-nine years, who had all his life enjoyed good health, noted two and one-half years ago some weakness in his shoulder muscles. A few weeks later atrophy of these muscles appeared. This paralysis and wasting have progressed steadily up to the present time. He has never suffered from pain. During the last two years he has frequently burned his fingers because of inability to distinguish hot articles.

Examination on March 1st showed marked scoliosis in the cervicothoracic region of the spine (which the patient stated had been present since childhood), great wasting of the scapular muscles and those of the upper arms, and, to a less extent, those of the lower arms and hands, and trophic changes in the hands, *viz.*, roughness and dryness of the skin and nails, vasomotor stasis, and a peculiar stiffness of the fingers. There is great loss of muscular power in the hands, arms, and shoulders, much more marked on the left than on the right side. Both knee-jerks are exaggerated and there is clonus in the left foot. The gate is spastic.

[1] The patient was presented to the Pittsburg Academy of Medicine, March 14, 1898, and to the Allegheny County Medical Society, March 15, 1898.

Tactile sense is preserved over all parts of the body. Over almost the entire body, except the face, the lower abdomen, the posterior portion of the thighs, half of the anterior portion of the right thigh and a strip running up the left side, he is unable to distinguish heat, or else is uncertain in his recognition of it. Over the entire body he recognizes cold objects brought in contact with the skin. Over the skin of the arms, trunk, head, and neck (not face), except over the lower buttocks and abdomen and left side, sharp pinches, needle-pricks, etc., do not give rise to a sense of pain, or only to a slight one. These areas of analgesia and thermo-anesthesia, it will be noticed, overlap in the trunk, arms, and head.

The accompanying diagrams, kindly made for me by Dr. Babb, indicate better than words the areas of anal-

Fig. 1.

gesia and thermo-anesthesia. Sensation has been tested several times, and I have to thank Drs. D. Moore, Jr., and George Holliday for assistance in this tedious work. The maps are, I believe, quite accurate.

Although syringomyelia is often difficult or impossible of recognition, yet when it presents the symptoms such as are seen in this patient, *viz.*, atrophy and loss of power in the muscles of the shoulder, girdle, and upper arms, trophic changes in the hands, scoliosis, and "dissociation of sensation," the diagnosis becomes plain, as much so as in any other organic disease of the cord. The "dissociation symptom," *i. e.*, the preservation of one form of sensation with the loss of one or more of the other forms, is no longer regarded as pathognomonic of syringomyelia, since its presence has been noted in

Fig. 2.

neuritis, hysteria, and myelitis. It must still be looked upon, however, as one of the most significant symptoms of syringomyelia, and its presence should always suggest the possibility of this affection.

THERAPEUTIC NOTES.

Recognition of a Deep Diverticulum of the Esophagus.—Reitzenstein (*Centralbl. f. Chir.*, Juiy 16, 1898) mentions the following means of diagnosis of a deep-seated large diverticulum of the esophagus, according to observations made upon a patient: (1) An obstruction to the passage of the sound which does not yield even after the tip of the sound has pressed against it for some time. (2) The chemical examination of the contents of the pouch will show an absence of ferments and free hydrochloric acid, and the presence of organic acids. It may also be possible to obtain from the diverticulum portions of a previous meal, while the last food swallowed has passed smoothly into the stomach. (3) In order to make a differential diagnosis between an idiopathic dilatation and a deep-seated diverticulum, it is necessary to pass into the stomach a sound whose sides are fenestrated

high enough to reach the diverticulum. If a second sound is passed and water poured into it, it will siphon off the whole of the water in case of a diverticulum, while if a diffuse dilatation be present not a drop will return. (4) If different colored fluids are used in two hollow sounds passed the one into the diverticulum and the other into the stomach, the second fluid will remain quite distinct. (5) Illumination by means of Einhorn's incandescent lamp. (6) Skiascopy after a fluid containing bismuth has been swallowed, or after the introduction of a sound filled with shot or powdered lead. (7) In many cases the sound of fluids rushing through is plainly distinguishable. (8) If a small solid sound whose tip has been wrapped with sticking-plaster be introduced into the stomach, and a colored fluid be poured into a second and hollow sound which reaches the diverticulum, the plaster will be colored if a diffuse dilatation is present, but not if there is a diverticulum.

Treatment of Gonorrheal Epididymitis with Ice.—UNNA (*Monatsh. f. prakt. Dermatol.*, August 1, 1898) says that for patients who can afford the necessary rest in bed, no treatment will so quickly and so surely relieve the pain and swelling of an acute or a chronic gonorrheal epididymitis as the constant application of ice. The principle involved is the expulsion of the exudate by the stimulation of the dartos muscle to its utmost power of contraction, and hence, the application of the ice must be thorough. The simple cooling of the skin will not suffice. For the correct carrying out of this treatment it is only necessary to provide several pounds of ice daily, a fairly large ice cap, a half yard of water-proof material, and a hoop. If it is not possible to keep the patient in bed constantly, considerable progress toward recovery may be made if the ice is applied at night only. Instruction should be given in the preservation of the ice, which will melt rapidly if it is not kept dry. The simplest method is to place a coarse cloth over a pail and to lay the ice upon it, covering it with a thick woolen cloth. The patient should lie upon a folded towel, the ends of which are to be brought up over his thighs, drawn tight, and fastened with a safety-pin. Upon the bridge thus made is laid the water-proof, and upon it the scrotum entirely wrapped about with the ice-bag. The latter should be filled only half full of medium-sized pieces of ice. So that it may readily fit the scrotum, a cloth wet with acetate-of-lead solution, and placed between the scrotum and ice-bag is grateful to the patient, and serves to distribute the cold equally. The hoop, fastened on either side of the bed keeps the clothing sufficiently elevated to allow evaporation, and prevents the rapid melting of the ice by the warm bed-clothing. By these simple measures the absorption of large exudates may be accomplished in a short time, and the patients cannot say enough of the comfort which the ice gives them.

If the ice is applied at night only, the scrotum should be wrapped daily in either waste gauze or should be bandaged with compression, or it may be simply painted with a ten-per-cent. ichthyol collodion.

This treatment with ice is beneficial, not only in inflammatory conditions, but in others in which the dartos is weak. Thus nervous patients or those with varicocele may use it at night with good effect, and its tendency is to promote sleep rather than to disturb it.

Treatment of Obesity by a New Preparation of the Thyroid Gland.—MACLENNAN (*Brit. Med. Jour.*, July 9, 1898) gives rules for the preparation of a new product of the thyroid gland, which, according to the reports of cases which accompany the article, may be used in the cure of obesity with greater certainty and safety than has been the case with the preparations of the thyroid gland hitherto on the market. The difference in the symptoms produced by the use of thyroid remedies by different persons is due probably less to their individual peculiarities than a difference in the preparations themselves. If one can have, therefore, a standard preparation of a known and certain strength, the possibility of reduction in flesh without the accompanying danger of sickness, diarrhea, sore throat, excessive sweating, and cardiac failure will be greatly increased.

The thyroid gland contains two important principles: one iodoglobulin, the larger constituent, and the other thyroiodin, discovered by Baumann. Both contain iodin, and both are requisite in order to obtain the specific effects of the gland itself. The best method for the separation of these active principles is as follows:

1. Selected and healthy glands are macerated in cold water, which extracts the soluble iodoglobulin. The solution is decanted or filtered off, and evaporated to dryness at a temperature of 212° F. The resulting powder is reduced to a fine state.

2. The residual glands are then boiled for an hour in a weak solution of caustic soda, which eliminates the thyroiodin. After filtration the solution is exactly neutralized with hydrochloric acid, evaporated to dryness, and powdered.

3. The two powders are mixed together, and constitute thyroglandin.

This preparation is made in such a way that thorough sterilization is secured, and the two important constituents of the gland are obtained in the same proportion as they exist in the gland itself, while other deleterious matters which may be present are excluded. If kept dry thyroglandin will retain its properties indefinitely without deterioration. It may be administered in capsules or tablets, in doses of 3 to 5 grains, such a dose being equal to half a gland of average weight.

Eudoxin in Intestinal Inflammations.—DR. SCHONLADNIEWSKI in the *Wiener Medicinische Presse* recommends in children from two to seven years of age, eudoxin in 3- to 6-grain doses for follicular enteritis, dysentery, and sub-acute, chronic intestinal catarrh.

Ointment for Pruritus.—

WHAT CONSTITUTES RESPONSIBILITY?

THE incidents that have attended the rounds of inspection recently indulged in by the Secretary of War and the Surgeon-General of the Army are calculated to awaken in the mind of the average person a somewhat confused notion of what "responsibility" means. The Secretary of the War when confronted with the charge that the quartermasters appointed by him are negligent, incompetent, and brutal, waves his hands in saintly innocence, and replies that he is very sorry, but of course he is not responsible. Well, here is a quartermaster upon whom the hospital surgeon, at a time of great sickness in the command (there being two thousand patients in the hospital), made a requisition for twelve fever thermometers, an instrument absolutely essential to the accurate diagnosis of typhoid fever. The answer comes back, "You're a chump," or something of that nature. "If you had asked for two I might have got you one." And this man cannot be disciplined or dismissed for he is responsible to nothing, except perhaps the wind, or the air, or his own sweet will. Neither is the Secretary of War responsible. With him this is not a world of responsibility. Events that happen here, even in the Quartermaster's or Commissary departments, are beyond the pale of human accountability.

Discovery is finally made, in this round of inquiry, that the medical officer in charge of the largest of all the volunteer camps, that of Camp Thomas at Chickamauga, at one time containing sixty thousand men, is a veterinary surgeon, who apparently knows nothing about sanitation or hygiene, and whose ambition has been to have a great division hospital where he should have personal supervision, and for which he should receive great personal credit. In pursuance of this plan regimental hospitals had been abolished, and two of the three surgeons constituting the staff of each regiment had been detached therefrom and ordered to the division hospital.

The result was that the surgeon left with the regiment (usually the second assistant-surgeon) had more work than he could possibly do in attending to the daily sick-list. The sanitation of the camp was neglected, filth and infection abounded, sickness multiplied, typhoid fever permeated the kitchen as well as the sinks, and the camp became simply a great source of supply to feed the hospitals with patients. In the meantime the hospital and regimental surgeons are being berated and denounced by the division commanders as incompetent and neglectful.

In this stage of affairs the question naturally arises, who placed a veterinary surgeon in supreme command of the medical and surgical department of the camp? The Surgeon-General answers that he approved and signed his application but that when he did so he did not know that he was a veterinary surgeon and, *therefore*, is not responsible. The Secretary of War on the other hand *does know* that Dr. Huidekoper came to him with the approval of the Surgeon-General and therefore *he* is not responsible.

Will these authorities at Washington be good enough to tell us what their acceptation of "responsibility" is?

RECENT VIEWS ON THE PHYSIOLOGIC FUNCTION OF THE THYROID GLAND.

THE function of the normal thyroid gland, the causes of the symptoms which develop in goiter, and the action of thyroid extracts upon healthy and diseased individuals are far from being well understood. Munk in a paper recently published in *Vir-*

chow's Archiv, maintains the position long since advocated by him, that the thyroid is an organ of secondary importance, and that the deaths and severe symptoms which follow its removal are not due to the lack of its secretion, whatever that may be, but to nervous disorder produced by the operation. He therefore looks upon iodothyrin as a substance which is not essential to the body. He reaffirms these conclusions from experiments which have recently been performed. Many animals recover after removal of the thyroid and continue in apparently perfect health. It is true that many of those experimented upon died, some of them after exhibiting symptoms of tetanus in varying degree; but these symptoms also developed after thyroidectomy in some animals having accessory thyroids which were not removed. Indeed, the results which follow the removal of the thyroid in animals are so varied that it is difficult to draw any general conclusion from them. Munk was unable to produce any effect whatever by introducing the thyroid gland into animals upon whom thyroidectomy had been performed, and he explains experiments of this sort which have been reported by others as errors of observation. While admitting that the removal of the thyroid gland predisposes to tetanus and is, therefore, a dangerous operation, he denies that the thyroid is in itself essential to life. Death often follows the removal of a thyroid which is functionally useless and may indeed occur during the operation. Under these circumstances it can scarcely be occasioned by the deprivation of thyroid secretion.

Some experiments by Exner point in the same direction. He found that removal of one-half of the thyroid in cats produced tetany provided the superior and inferior laryngeal nerves of the opposite side were divided, either at the time of operation or soon afterward. The same result followed division of these nerves upon both sides without removal of the thyroid gland. In the animals treated in this manner there was no change in the normal amount of iodin present in the thyroid gland, at least up to a period of two weeks after the date of operation. Exner, therefore, regarded the symptoms which follow thyroidectomy as having a neurotic rather than a secretory genesis.

In marked contrast to the modestly indefinite views of these authors are the theories advanced by De Cyon. He states that the action of the thyroid gland is to convert the salts of iodin which are present in the blood into iodothyrin. The former are depressors of the heart, while the latter is a stimulator; hence, the heart is able by means of the connection through the laryngeal nerves, to regulate the activity of the thyroid gland and thus indirectly to control its own action. The thyroid gland also protects the central nervous system against too great pressure by offering, when its vessels are dilated, sluiceways for the surplus blood. This action is also under control of the heart.

Some experiments by Berard in thyroid fever are interesting in this connection. He found it present in twenty-one out of thirty cases after thyroidectomy. The general characteristics were as follows: On the evening after operation, or perhaps on the following day, there was a sudden rise of temperature to 102° to 104° F. This continued with regular morning remissions for eight or ten days, when by crisis or lysis the temperature curve returned to normal. The general condition often did not correspond to the amount of fever. Sometimes the pulse was 110, the respiration 30, with an increased perspiration, trembling, and a feeling of heat, so that the general picture was not that of a severe infection, but rather that of an intoxication due to a temporary excess of the products of the gland in the blood. Glycerin extracts of hypertrophied thyroid gland were injected into the veins of seven rabbits and produced fever, rapidity of pulse and respiration, diarrhea, contractions in the palms, and increased reflexes. Normal thyroids, when injected, produced an increase of temperature but no other symptoms, so that apparently a hypertrophied thyroid gland secretes abnormally toxic substances.

Magnus-Levy discusses in the *Zeitschrift für klinische Medicin* the effect of thyroid extracts upon the metabolism. He found that thyro-iodin has a much more powerful influence upon the metabolism than the inorganic salts of iodin. Its influence is not exerted upon every one whether sick or well. It reduces weight by a loss of water and albumen, and also by a true destruction of fatty tissue. This is, however, of the nature of poison and on this account and because complications of a nervous character are often associated with reduction in weight the writer thinks that the thyroid cure for obesity is unwise.

ECHOES AND NEWS.

Health of the Troops in Porto Rico.—The sickness in the army of occupation at Porto Rico is still increasing. The latest reports announced that there were 2500 soldiers under treatment. Typhoid fever and malaria are the prevalent diseases.

Yellow Fever in the South.—At Franklin, La., the total number of cases reported by the Marine Hospital Service up to September 13th was forty-two, with two deaths. At Jacksonville, Miss., September 10th one case; at Orwood, Miss., from July 30th to September 6th, forty-one cases with no deaths.

Cornell University Medical School.— The opening exercises of this institution will be held in the amphitheater of the college building, Tuesday evening, October 4th, beginning at 8 o'clock. An address will be delivered by President Schurman of the University and by Dr. Polk, dean of the faculty.

New York Polyclinic Medical School and Hospital.—The winter session of this institution began September 15th. The faculty and staff are meeting their appointments with their usual promptness and regularity, and the number of students already in attendance gives promise of a most successful winter.

Dr. Senn's Panacea for Military Shortcomings.—The most flagrant fault had its seat in the dependence of the medical department upon the quartermaster and his men. The medical department must have its own lighters, its own transports, its own mules and wagons. The entire system as now used must be revolutionized. As the first step, the Surgeon-General should be elevated to a Major-General's rank and pay.

Sickness in the Philippine Army.—The 13th Minnesota Regiment which is stationed at Manila has forty-five men on the sick-list. Three privates belonging to that regiment died during the week ending September 22d. General Babcock, who arrived at San Francisco September 22d on the steamship "China" from Manila, says that the Spanish soldiers of Manila are quartered in the cathedrals and churches; the Philippinos wherever they can find space. All of our soldiers are in the barracks and well cared for.

Smallpox at Put-in-Bay.—About the middle of August smallpox developed among the servants at the Victory Hotel at Put-in-Bay, Ohio. The Marine Hospital Service reports that up to September 6th there had been twenty-six cases, twenty-one of the patients being negroes. Most of the negroes came to the hotel from Asheville, North Carolina, and undoubtedly brought the disease with them. This outbreak is evidently a side issue of the somewhat general epidemic of smallpox throughout the Southern and Southwestern States.

Medical Services at Auction.—The Bingly (England) local board is obliged by law to have a medical officer of health. Quality with them does not count; the price is everything. Accordingly it has issued an advertisement, the form of which leads to the inference that the man who places the lowest money value upon his services will be selected for the position. The officers of that community must certainly have strange ideas regarding the commonest courtesy due to members of a learned profession, for certainly nothing could be more insulting to the medical profession.

Red-Cross Work Commended at Jacksonville, Florida.—Each day the Red Cross gives 50 gallons of milk, 2000 pounds of ice, and 30 dozen of eggs. Besides this it has built store-houses, floored the tents, given hundreds of night-shirts, pajamas, pillows, sheets, buckets, bedpans, and dozens of other articles necessary for the care of the sick. In military channels the stream of supplies flows slowly and with many stops and much formality, but Dr. Kent, who represents the Red Cross at Jacksonville, gives freely and without delay. He has no regulation that prescribes how many bedpans one division must use, but gives all that are needed.

Casualties in the Soudan Expedition.—In the recent fight at Omdurman there were 4 officers killed, 3 English and 1 native, as well as 23 men in the British regiments and 20 in the native. There were 14 British officers wounded, and 8 native officers. The wounded in the British regiments numbered 99, and in the native regiments 221, so that the total number lost in this battle—in which the enemy lost some 15,000 in killed and wounded—was 389. Lieutenant-Colonel Hoggett, senior medical officer of the expedition, received a bullet wound of the left breast, and 2 men of the corps were wounded, one of them severely, by a bullet in the head.

Responsibility for the Hospital Surgeons and Their Work.—General Breckenridge recently submitted the direct question to General Sternberg as to who had the right to command the hospital surgeons, saying that, at Chickamauga, these individuals were a sort of do-as-you-please fellows under nobody's command. The same condition existed at the new quarters at Camp Hamilton. General Sternberg replied that the surgeons were subject to the orders of the division commanders; that it was the latter's business to know this and secure obedience. The surgeons had maintained that they were responsible only to Surgeon-General Sternberg.

Medical Practice in South Africa.—The correspondent of the *Münchener Medicinische Wochenschrift* writes that the number of doctors is increasing out of all proportion to the population. The expenses of living are also on the increase. It is high time, therefore, to warn some of our younger brethren who are anxious to make their fortunes in as short a time as possible that Africa does not hold out the golden palm as in days of yore. There seems to be unlimited scope for the unqualified practitioner. Johannesburg appears to be overstocked with "doctors," the majority of whom have had no medical education whatever; these satisfy their consciences by buying diplomas on the spot. A license to practise is given to any one who pays $100.

The Soudan Expedition.—The *British Medical Journal*, in commenting upon the success of the Soudan Expedition under Sir Herbert Kitchener, remarks that the most difficult part of the advance was over long before the two forces stood face to face. The great merit of the Commander and of his staff has been the frank recognition of the necessity for forming a true estimate of the risks to health involved in moving a large force for so great a distance under a trying climate and under local conditions as to the water-supply and camp grounds, which rendered it imperative that every move should be regulated by sanitary requirements. The success of the advance reflects the greatest credit on the medical officers who have advised on these points and upon the Sirdar (Kitchener) who has known how to value and accept their advice.

More Sick Soldiers from Cuba.—When the "Vigilancia" arrived about three weeks ago at Montauk she reported that she brought the last of the sick from Siboney and Santiago, but on September 21st there arrived unheralded at Montauk the transport "Segurança," having on board forty men in good condition and thirty-five ill. One of them was a yellow-fever patient. This transport announced also that she brought the last of the sick. Four hours later the transport "Mexico" arrived and made the same statement regarding herself. She brought seventy-six men of Troop M., 10th Cavalry, and eighteen sick. Both transports were ordered immediately to New York quarantine. There the yellow-fever patient was placed in the hospital at Swinburne Island, and all the other passengers on Hoffman Island for disinfection and detention. The yellow-fever patient has since died.

Surgeon-Major Pinches.—The following incident is told of Surgeon-Major Pinches, who was attached to the 21st Lancers in the Soudan campaign. Out of a total strength of 320 men with which the regiment went into the battle at Omdurman no fewer than 40 were killed and wounded. Several horses were quickly hamstrung and their riders were promptly cut to pieces by the ferocious foe. With but one exception no man who was once actually unhorsed was again seen alive. This man was Surgeon-Major Pinches. His horse was brought to the ground and the officer fell among the furious dervishes. Sergeant-Major Brennan, who was riding ahead, saw the Major's peril and gallantly returned to his assistance. After a tough fight, in the course of which several dervishes lost their lives, Brennan succeeded in getting the officer on to his own horse and back to the regiment.

Facts Concerning Dr. Huidekoper.—One who knows writes us as follows: As a young fellow, Dr. Huidekoper had a good training and was one of the junior surgeons at the University of Pennsylvania, with fine prospects. Pepper induced him to go to Alfort, where he spent three years at the veterinary school. Returning, he organized the Veterinary Department of the University of Pennsylvania. Though he gave up his medical practice, he always mixed with medical men, and he was surgeon to the City Troop, and for many years in the National Guards, where he had excellent opportunities for knowing the routine of camp organization. It is very unjust to speak of him as an obscure veterinary surgeon, for few men in this country have done more to promote its highest interests, and I know personally the character of the work he did in Philadelphia, and the self-sacrificing way in which he labored for the school. I do not defend his appointment, but we should be just to him.

The Medical Club of Berlin.—Dr. J. M. Winfield writes to the *Brooklyn Medical Journal* concerning the above named medico-social undertaking at the German capital. "The men who have inaugurated this club have brought out a very unique thing. They have a number of rooms furnished and equipped in club style. Meals are served to members, and all visiting doctors from any part of the world are invited to visit and use the club as their headquarters when in the city. Some of the waiters speak English, so an English-speaking doctor can always feel at home. In addition to the restaurant, card- and billiard-rooms, they have a spacious reading-room and library, where all of the medical journals of the world are kept on file. The president is Dr. Lesser, one of the best-known professors at the University. The medical men in Berlin are very anxious to make the club a success, especially for foreign visiting physicians. It costs for visiting members three marks per month, less by the year."

The Regimental Hospitals Restored at Camp Poland, Lexington, Ky.—Under the administration of Colonel Huidekoper, the veterinary surgeon who had charge of Camp Thomas at Chickamauga, all of the regimental hospitals were abolished and all of the sick of the entire army of 60,000 men were transferred to the division hospitals so that they could be under the immediate supervision of Colonel Huidekoper. Upon the recent visit of Secretary Alger and General Sternberg to this camp Colonels Gardner, Kuert, Lawton, Shuble, and Young, and Major Schaffer objected strongly to the abolition of regimental hospitals, and Surgeon-General Sternberg directed that these should be restored. Colonel Huidekoper accompanied the troops from Chickamauga to Porto Rico, and against the strong opposition of the regimental commanders insisted on applying his system there, abolishing regimental hospitals and forcing all the sick into a division hospital, where, as Colonel Huidekoper said, it enabled him to keep all the sick under his personal supervision.

Deaths under Anesthesia.—Two deaths near Birmingham, England, during the administration of anesthetics have recently been reported. One was that of a boy aged fifteen years who died under chloroform while undergoing an operation on a diseased hip-joint. Chloroform was administered in a modified Junker's inhaler; only 80 minims were given, the operation lasting twenty-five minutes. Previous examination showed no contra-indication to the use of chloroform. Post-mortem revealed a normal but contracted heart. In the second

case the patient was a woman, aged thirty-nine years, suffering from cancer. The anesthetic was a mixture of chloroform and ether. Preliminary examination failed to disclose any contraindication to the anesthetic. On post-mortem a flabby, fatty heart was discovered. The patient died in the first stages of the anesthetic before the operation was begun. A third instance of death under anesthesia is reported from Liverpool. The patient was a workman aged twenty-eight years, who was about to be submitted to an operation for the repair of a crushed hand. Autopsy revealed no sufficient cause for the fatal termination.

The President's Investigation Commission.—This commission began its regular sittings on Saturday. September 24th. Many of the men selected to serve upon it have declined but those who have undertaken the work are the following: Major-General Grenville M. Dodge of New York; Colonel J. A. Sexton of Illinois; Captain E. P. Howell of Georgia; Major-General J. M. Wilson, Chief of Engineers of the United States Army; Charles Denby of Indiana, former Minister to China, former Governor of Vermont; former Governor James A. Beaver of Pennsylvania; Major-General Alexander McD. McCook, U. S. A., retired, and Dr. Phineas D. Connor of Cincinnati, Ohio. It is thought that the commission will make its first inquiries in the Secretary's office, the Adjutant-General's office, and the office of the Major-General commanding the army, taking cognizance of the orders which were issued for the conduct of the war and the instructions given to the army. In the same manner the offices of the Surgeon-General, Quartermaster-General, and Commissary-General will be examined into to ascertain the character of the orders issued, and whether they were carried out. It is not known whether the commission will visit the camps, but it is thought probable that such journeys will be made.

Some Camp Thomas Items.—One of the surgeons at Camp Thomas says he made a requisition for two dozen fever thermometers with which to take the temperature of a large number of sick soldiers. The curt reply came back from an official upstart: "If you had made requisition for two thermometers, instead of two dozen, we would have tried to get one for you." It was not until General Breckenridge took command at the camp that lime was used to disinfect the sinks that had made Chickamauga Park a breeding-place for malaria and typhoid fever. There was a great lack of good drinking-water for several weeks. Several nurses testified before Major Ward and his associates that no orders were issued to wash the sick men, and there were no conveniences furnished for their washing. And so they suffered, and in many cases died in conditions too horrible to describe, outside of a medical journal. The hospitals lent new horrors to death. Many who perished would probably have suffered less had they been left to die in the open air under the shade of the trees. . . . It seems incredible that in this land of plenty scores of fever-stricken soldiers at Camp Thomas should die without being supplied with the ice and milk for which they pathetically pleaded. Yet there is sworn testimony to this awful fact. Speaking of this matter, a leading citizen of Chattanooga said to me: "This is a great milk country about here. There are cows enough in this section to supply milk for an army in addition to the men who craved for it in the camp hospitals. There are two artificial ice-plants at Chattanooga that could have been purchased by the Government, and could have been made to turn out more ice than the hospitals needed."—*Brooklyn Eagle.*

CORRESPONDENCE.

A PREVALENT METHOD OF INFECTION AMONG CHILDREN.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In the wonderful progress of the science and practice of hygiene that has come about during the last ten years, it seems strange that such a ready method of infection, as is furnished by children when transferring already salivated foodstuffs from one mouth to another, should escape scrutiny, comment, and condemnation. This filthy and positively dangerous habit, though innocently practised is a matter of paramount importance and demands more than passing attention.

This evil, the effects of which are highly detrimental, cannot be abolished till the public attention and fear are aroused by impressing on their minds the positive dangers connected therewith. Mothers must strenuously oppose the injurious habits of their children eating from other children's mouths. Further, in schools, and especially in the playgrounds where this innocent vice is practised to its fullest extent, teachers should be on the alert to reprimand such victims. Is it too much to ask that the "Board of Health" shall at once take decisive steps for the prevention of this pernicious vice?

MAURICE MINTON, M.D.,
39 MONTGOMERY STREET, NEW YORK, September 26, 1898.

VOLUNTEER OFFICERS AND THEIR MEN.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—I beg to inquire if your attention has been called to the comparatively low rates of sickness and death (except in battle) that appear to have been incident to our officers of volunteers who have returned to us from both the conquered Spanish territory and from the camps at the South? The terrible losses and suffering that have, in so many places, befallen the private troops have apparently given their officers the go-by. I say "apparently" for the reason there has as yet been published no official statement that would enable us to form an exact opinion. I have had this subject before my mind for some time past and have formed an opinion, from what I have read, that not only has sickness and loss been proportionately less severe among volunteer officers than among their men, but also among the officers of regulars.

I trust that some trustworthy research may be made, officially or otherwise, to throw light on these apparently different loss-rates for different classes of men, and inci-

dentally to give information as to the dietary of officers and men while at the front and at the instruction camps. This research may result in bringing to light some very selfish conduct on the part of the officers, if the truth is ever brought out from a class of men who are very slow to make complaint. I chanced to overhear a trolley-car conversation turning upon the conduct of many of the officers of the 71st New York Volunteers, that made it plain that the boys of that regiment were imposed upon by their officers at every opportunity, and further, that there is a day of reckoning to come for those who maltreated their men. LUX.

Brooklyn, September 19, 1898.

[This fact has evoked frequent comment on the return of the various regiments, not only from Cuba but also from the volunteer camps. The lack of consideration shown their men by some volunteer officers was depicted in the "Pen-pictures of Camp Wikoff" published in the MEDICAL NEWS September 10th. This charge suggests a very proper field for official investigation.—ED.]

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

REQUIREMENTS OF PRELIMINARY EDUCATION AND MORE RIGID MEDICAL EXAMINATIONS—HOSPITAL BEQUESTS—PERSONAL NOTES—HOSPITAL NOTES—PHILADELPHIA COUNTY MEDICAL SOCIETY MEETING—HEALTH STATISTICS.

PHILADELPHIA, September 28, 1898.

THERE is some little speculation as to how the law requiring "a competent common-school education" as preliminary to the study of medicine is to be interpreted, and a commission appointed from members of the public-school boards to hold these examinations will probably have some difficult problems to solve, and the enormous and constantly increasing number of matriculates at the medical schools demands more care in this matter and a more rigid system of examinations by the State.

Dr. Henry Beates, Jr., a member of the State Medical Examining Board and an ardent worker for a high standard, furnished the following examples as illustrative of material which frequently comes before the board, the questions and answers here given being verbatim copies of some sample answers in the examinations of applicants for a license to practise medicine in this State:

Question: "Describe the functions of the capillaries."

Answers: "They carry the air and blood through the tissues and organs." "Carry nutrition, oxygen; carry away waist-products; assist in radiation. They give a rich blood-supply to the parts. They carry red and white blood-corpuscles to build up injuries; carry off waist-products, and is in generaling the temperature of body by their power of contractility." "To supply nourishment to the superficial surfaces of the skin, and to assist in carrying oxygen to the lungs."

Question: "Give the origins of normal fat in the human body, and name examples of the types of food from which it is elaborated."

Answers: (1) "Due to imgration of fat cells and blood-corpuscles. (2) Meats, sugar starches." "The circulation and lymphatics along with the starches. Animal foods." "In liver fat; is found normally of long bones from meat. Hydrocarbons and carbohydrates. Fat and oils from liver substance its self."

Question: "Describe the pathological changes in senile gangrene."

Answer: "The tissue undergo changes by the extravasation of leucycites and cellerlar tissue change, which causes death to the part."

Question: "Summarize the function of sweating, and explain the office of each physiological factor concerned."

Answer: "The function of sweating are, the kidneys which carry of the sweat which is not gotten rid of through the skin the pores are also means of getting rid of the sweat, and it is also absorbed by the hair follicles."

Question: "Name each anatomical structure involved and describe the changes occurring in tubercular arthritis."

Answer: "The lungs become involved when the tubercle is contracted it involves the spleen, becomes congested, the liver being inflamed."

Question: "Describe metabolism."

Answer: "Metabolism is a system of waste and repair; it is constructive and distructive, it influences heat, light, moisture, and electricity."

Question: "Describe the pathological changes in acute yellow atrophy."

Answer: "There is fatty degeneration and escapement of cellular elements."

Question: "Describe the pathological conditions present in peritonitis."

Answer: "There is hyperemia of the serious membrane the capillaries distended and occasional extravasation of blood from the rupture, the normal secretion is arrested, the shinney membrane becomes dull and opaque from exudation of pure fibrin which is adhesive glueing the parts together this is adhesive peritonitis if it goses on the effusion of serious fluid is poured into peritoneal cavity it is called exudative."

Question: "Name and describe the various forms of white cells of the blood; methods of differentiation, and their pathological significance."

Answer: "they are diferented by the microscope the one will be a white cell while the other will be a white cell with a small round dot either in the center or at the sides which can be distinctly made out. they are the scavengers of the body and they will try to kill bacteria which enter the body for instance if you have a wound they will flock there and battle with the bacteria and die and raise a monument and the monument will be the scab.

"P. S. These cells are called the leucocytes, microcytes."

Another answer was: "I know of but one kind of white blood-cell although they change their form very much and afterward assume their round shape again unless distroyed by the function which they have had to perform. Their significance might be determined by the aid of the microscope for as their function is to act as guardians and

scavengers it might be determined finding out what they may be trying to dispose of."

By the will of the late Catherine Thorn the following bequests are made: To the Episcopal and Pennsylvania Hospitals $5000 each in memory of her husband and brother respectively, and to the Home for Incurables $3000.

Dr. Keen returned from Europe last week and immediately went to Washington to confer with the President about the War Inquiry Commission on which he finally determined not to serve. Dr. Emil Dippel, who was so severely blood-poisoned early in the summer, has resigned from St. Timothy's Hospital.

Dr. John B. Robert's resignation as President of the Philadelphia Polyclinic and College for Graduates in Medicine has been accepted with regrets by the Board of Trustees.

Dr. Gans, Assistant Surgeon of the Twentieth Pennsylvania Infantry, has been appointed Medical Director of a hospital for convalescent soldiers, established by the Pennsylvania Women's Emergency Relief Association, with Dr. M. V. Leaf as assistant.

Dr. Hare held the first medical clinic at Jefferson Hospital last Monday and Drs. Hearn and J. Chalmers Da Costa, surgical clinics.

Of the 1550 sick soldiers received at the different hospitals throughout the city, 365 have been discharged and 24 have died, a mortality thus far of 1.6 per cent.

The remodeled laboratories of Jefferson Medical College are almost completed and will be occupied the first of next month, while the new college building is so far advanced as to leave no doubt of its completion by June, 1899, the time specified in the contract.

The daily papers last week published the fact that gangrene of the skin had appeared among the convalescent soldiers in St. Agnes' Hospital. Dr. B. Franklin Stahl of St. Agnes' ascribes it to the inconceivable weakness of the soldiers' blood and consequent malnutrition, a condition difficult to overcome in typhoid convalescents. Two deaths have already occurred.

The Philadelphia County Medical Society held its first fall meeting September 14th, papers being read by Dr. Roberts, who reported three cases showing "The Necessity for Early Operative Interference in Intestinal Obstruction," and by Dr. S. Solis-Cohen, whose paper on the "Treatment of Exophthalmic Goiter with Suprarenal Substance" was discussed by Dr. J. Coles Brick and Dr. J. Chalmers Da Costa.

The total number of deaths for the week ending September 23rd, as reported at the health office was 376, of which 120 were in children under five years of age. The total number of contagious diseases reported was 480, as follows: Diphtheria, 99 cases with 17 deaths; scarlet fever, 15 cases with 2 death; typhoid fever, 366 cases with 15 deaths.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

GERMAN MEDICAL SCHOOLS AND THE INVASION OF SPECIALISM — A SPECIAL APPLICATION OF THE ELECTIVE SYSTEM IN MEDICAL WORK — WANDERJAHRE IN MEDICINE AND OPPORTUNITIES AFFORDED—POSSIBILITIES OF THE SYSTEM IN AMERICA.

Berlin, September 18, 1898.

About the time this reaches you American medical students will be finding their way back to the medical schools for the year's work. German medical students will not begin the semestral work until after November 1st. Meantime October, in many of the German university towns, and especially here at Berlin, is taken up by a series of special vacation courses, attended by recent graduates and medical undergraduates who are entering on their final semesters. The specialism of modern practice invades the sacred domain of even a German university medical career. The protest voiced so forcibly by Professor Von Jaksch at the German Medical Congress at Wiesbaden in the spring, during the discussion of the clinical aspects of medical education, was echoed by distinguished German professors, who had scented the danger, too, but courses in the specialties are of too intensely practical interest to the student, who looks forward to practice shortly after graduation, to permit them to be neglected for the sake of the supposed firm foundation afforded by nine semesters of exclusive application to the principles of general medicine and surgery. It is not alone in the vacation courses but also in the regular university courses that the invasion of specialism even in student days is noticed and its satisfactory limitation is evidently going to constitute one of the serious medical educational problems of the Twentieth Century.

Meantime there is a very common custom among the German students that protects them more than is usually the case from the seductions of premature specialism and lends an added interest to the study of the fundamental principles and the cognate sciences that constitute the important groundwork for a medical education. Very few German medical students take all of their medical courses at the same university. Very often the first semesters are passed at one, often at several of the smaller universities, the last semesters being taken at one of the larger universities, situated in a large town, and so supplied with abundant clinical material for the important practical work of the final medical courses.

The method is, of course, entirely unfamiliar in America and at first only its disadvantages may be evident. It might seem that a much more full and rounded course would be obtained by constant attendance at one university where special attention had been given to the arrangement of the different subjects properly in various years, than by attendance at various universities whose courses have been arranged without reference to each other. This objection would be truer in America than it is in Germany, where all the universities are government institutions, and where all the teaching methods are modeled, as far as practicable, after a common plan. Even in the best medical schools of the United States,

however, it is probable that very little of importance would be missed if the different years were passed at different schools.

The method enables the German medical student to become personally familiar with the great makers of medicine in the various lines of medical thought and at the same time to learn something of the spirit of various German univerities. For, though all recast in the modern mold of present-day government university regulations, German universities have an individual spirit, the outcome of centuries of tradition in many cases, that is essentially distinctive. The broadening influence of this familiarity with men and cities, with methods and manners, can scarcely be overestimated, and it represents a factor in the educational formation provided by German universities that must always be reckoned upon if we are to estimate fairly the development they set in action.

Many, of course, and varied are the motives that impel students to the selection of certain universities for certain semesters. Those who are especially interested in anatomy, histology, and embryology may elect to pass their semesters in these branches at Berlin because in these subjects Waldeyer and Hertwig are names to conjure with. Those who are interested in practical physiology and its applications to clinical medicine pass a semester under Landois at Greifswald. Von Recklinghausen at Strassburg, Orth at Gottingen, Grawitz at Greifswald draw students who are or hope to be specially interested in pathology. Heidelberg gets certain medical students who are interested in surgery or nervous diseases because Czerny and Erb are there. Those who see a great future in clinical medicine for physiological chemistry, scarcely fail to pass at least a semester at Strassburg, where Winkowsky is doing such practical work in physiology and Naunyn is showing the practical application of physiological chemical principles to metabolism in health and disease.

We might continue the enumeration until the list of great German workers in medicine was exhausted. The names became familiar to German medical students very soon because there is from the beginning the question as to which teacher should be selected as the master in special branches. The very fact of having in a way to learn various men's views, to look over their books, to inquire of fellow students as to the success of their teaching methods (for they recognize here that the great scientist may prove to be anything but a great teacher), the problem of having to size up, so to say, whose *ipse dixit* seems worth being magistral in the formative stage,—all this gives a broadness of view that in medicine especially is part of the highest training. It does not degenerate so easily into that hypercriticism of other schools and other methods in medicine that is founded on imperfect and defective knowledge of men and their principles. It cultivates, yet not too precociously nor superciliously, that liberal eclecticism that seems to constitute the best basis of modern practical medicine.

Of course German medical students are not always guided by the lofty motives of pure scientific zeal, nor the more sordid ones of practical prospective utility in their selection of certain universities for certain semesters. They may go to Marburg or to Jena because Behring or Haeckel are there; yet an additional motive may be that the corps-student spirit runs high, that there is a traditional spirit of student gaiety about the universities, celebrated in song and story, that makes one wish to have pleasant recollections, that intertwine with the storied memories that cluster around the old places and are redolent of the times when great literary or scientific genius trod paths that have become so familiar. The German student may go to Greifswald because he wishes to take a course under Mosler, most magnetic of masters, though it may only be that he hopes to find the summer semester pleasanter on the shores of the Baltic Sea. He may go to Bonn because of Pflüger's physiology, or Binz's pharmacology and therapeutics, though he may go only because it is an extremely fashionable university, where crown princes and nobles go, or it may be that he wishes to subject himself for a semester to all the subtle magic of the Rhineland and its scenery and learn to appreciate its beauties.

Even when motives as seemingly adventitious and impertinent as these play a rôle in the selection of the universities at which various semesters are to be taken the result of the university career is eminently promising. There is a wider knowledge of men and methods inevitably acquired; there is the liberalizing influence of association with what is best in German educational circles; above all, there is the obliteration of the tendency to accept routinely the dicta of any school just because they happen to be emanations from that school and without the formality of personally testing their reasonableness.

Besides these more or less impalpable but very definite advantages there is the material advantage in climatology and in hydrotherapy; of knowing in various parts of the country health-resorts, and bathing- and watering-places, not as mere names, but by actual inspection and some personal experience. On the whole, a wandering American who studies the workings of the system is inclined to think it would be a source of good in America, too. The ordinary medical graduate about to take up the routine of practice would be much better fitted for a successful career by a knowledge of the men and methods of three great medical schools than of one. He might have failed to know in his last year the exactly contradictory answers that he should have given to the two professors of practice if they both happened to ask a certain question on which they disagreed. He might not know much about a number of useless drugs that the fad of a special professor of therapeutics still insisted on keeping in the program of study, though no one, not even himself, used them. He might not know the details of the last operation invented by one of his professors of surgery, but condemned by the other. In a word, the medical graduate might not pass his examinations as well, but he would be much better prepared to begin to select his practical opinions for himself. He would have had an initiation into that all important problem for the medical man, what opinions in the midst of those that are continually being put forward are worth the while stop-

ping to consider at all, and which of them are worth trying out on their merits. The critical faculty so necessary in medicine would have been called into action and a liberality given to its special applications that would promise much for the rational application of medical principles, and would not permit its possessor to be blown about by every wind of medical doctrine that came bearing with it some supposedly great medical name. We are only entering the Twentieth Century, however, not the millennium, but let us hope for the best.

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Eleventh Annual Meeting, Held at Pittsburg, Pa., September 20, 21, and 22, 1898.

FIRST DAY—SEPTEMBER 20TH.

MORNING SESSION.

THE Association met in the assembly hall of the Monongahela House, and was called to order by the President, DR. CHARLES A. L. REED of Cincinnati, Ohio, at 10 A.M.

DR. JOHN MILTON DUFF of Pittsburg welcomed the Association on behalf of the local medical profession. Lieutenant-Governor Walter Lyon followed with a brief but very eloquent address of welcome on behalf of the citizens of Pittsburg and of the State. President Reed, on behalf of the Association, responded to these remarks of welcome in a very concise, but graceful speech.

Following the preliminary exercises came the first paper of the scientific session, by DR. FREDERICK BLUME of Allegheny, Pa., entitled

SOME OF THE COMPLICATIONS FOLLOWING HYSTERO-SALPINGO-OOPHORECTOMY IN PELVIC SUPPURATION; WITH REMARKS ON THE OBJECTIONS TO THIS OPERATION.

He said a perusal of the literature of the past few years proved that vaginal hysterectomy had made its way here and abroad. Its condemnation upon theoretical grounds had decidedly diminished. Its advantages were too plain to permit of being longer ignored. Men who, in the beginning, strongly objected or opposed this mutilating operation, as some were fond of styling it, had changed their opinions. Guided by the experience of others they had adopted this method and confirmed the assertions of its advocates that it was a conservative operation in the broadest sense of the word—a procedure which, though sacrificing the uterus, conserved the life of the patient even under circumstances where the suprapubic route would mean certain death.

The propriety of removing the uterus in suppurative disease of the appendages had been questioned ever since Péan introduced vaginal hysterectomy. Briefly stated, the chief objections were: (1) the uterus was not a useless organ after the ablation of the appendages, and should not be sacrificed unless seriously diseased. (2) Vaginal hysterectomy was an incomplete procedure, followed by serious complications and was not curative.

The disposition to preserve the uterus during the child-bearing age in women with healthy tubes and ovaries, or in unilateral suppurative pelvic disease could well be understood, but why this organ should not be removed as the initial step of a life-saving operation, when the ablation of both appendages became a necessity was beyond comprehension. The assertion that the uterus without the appendages was still an important organ; that its functions had not ceased with the artificial induction of the menopause must be rejected as untenable in the light of present knowledge. The arguments that after the extirpation of the uterus the nervous phenomena were more pronounced than when the appendages were left alone, had strongly influenced many surgeons against vaginal hysterectomy. Careful investigations, however, had shown that these arguments could not be verified. Mainzer, in a report of 200 vaginal hysterectomies for chronic inflammation of the adnexa, performed in Landau's clinic, had arrived at the conclusion that there is less disturbance of the nervous system after the radical operation than after salpingo-oophorectomy alone. He further states that the age of the patient bears no relation to the presence or absence of these nervous symptoms.

Dr. Blume does not confirm the view that the removal of the uterus increases the nervous disturbances incidental to the menopause, and he is inclined to believe that this view is based upon the complaints of neurotic women. As to the sexual passion his patients, with but one exception, state that they have as much sexual appetite now as at any time before operation. Two of them, young widows, who married a year after the operation, informed him repeatedly that they were more passionate and enjoyed sexual intercourse more than ever.

The mortality of vaginal hysterectomy was considerably less than that of the abdominal operation. There was, however, a diversity of opinion as to the ultimate results of the vaginal procedure. The essayist does not resort to the vaginal method in those cases in which there is a possibility of saving one tube and ovary, *i.e.*, in cases of unilateral suppuration even when due to gonorrhea. He is not yet convinced that both appendages must be sacrificed, far less the uterus, when gonorrheal infection is limited to one tube and ovary. His personal experience with vaginal hysterectomy for pelvic suppuration is limited to 42 cases during the years 1895, to September, 1898. This series, though small in number, was quite interesting on account of the extent and the gravity of the pathological changes. Of the 42 patients, 18 belonged to that desperate class which, if treated by the abdominal route, were either left unfinished or, according to the statements of prominent operators, had a death-rate of 25 to 30 per cent. in the hands of the most skilful surgeon. The pelvic organs were agglutinated into one mass and could not be distinguished by vaginal or rectal examination. In some instances these masses reached half way to the umbilicus; while in others the peritoneal cavity was less involved and they extended downward into the vagina, pushing the

uterus against the symphysis pubis and compressing the rectum to such an extent that an ordinary rectal tube could not be passed without difficulty. The lesions of the remaining 24 patients were not quite so extensive, yet in every instance both appendages were so far involved that a conservative operation was out of the question. Complications occurred in three cases.

DR. JOSEPH PRICE of Philadelphia said that the sexual appetite of women, alluded to by the essayist, following a variety of operative procedures, was in many instances improved rather than impaired. It was rare for a woman to complain of impaired sexual appetite after a supravaginal hysterectomy. Age, however, should be considered in discussing the nervous phenomena incident to a normal or precipitate menopause. He advocates the abdominal route, saying that the vaginal method was an incomplete one. The latter method favored bowel obstruction. Of ten vaginal hysterectomies performed by Coe in his early work, there were two deaths from intestinal obstruction.

DR. EDWIN RICKETTS of Cincinnati cited an instructive case in which it became necessary to resort to the combined method. He spoke in favor of the vaginal route in some cases, but not in all instances for pus in the pelvis.

DR. RUFUS B. HALL of Cincinnati was willing to admit that there were cases that could be dealt with by vaginal section and drainage, but the field for this operation was limited. In cases in which there were dense adhesions to the viscera good, complete work could not be done by the vagina. Experience had taught him that if a patient was under thirty-five and the uterus was removed by an abdominal operation and the cervix was left, she suffered less from reflex disturbances than she did when the uterus was left.

DR. CHARLES GREENE CUMSTON of Boston said that suppurative conditions within the pelvis demanded different treatment, according to their situation, the number of foci, their size and nature, and in making the diagnosis and considering the choice of operation, all of these things should be considered, whether the case be suitable for the vaginal or abdominal route. In most cases of pus in the pelvis, speaking in a broad sense, posterior colpotomy was a trifling operation, yet a conservative one. It could be performed in cases of chronic purulent disease of the female pelvic organs and in acute suppurations where it would be dangerous to do either abdominal or vaginal hysterectomy.

DR. JAMES F. W. ROSS of Toronto said that at the Montreal meeting of the British Medical Association vaginal hysterectomy for cancer was discussed, and his experience agrees with that of Price, that this operation for carcinoma, no matter how early it was done, was not satisfactory. High amputation of the cervix after the method of Byrne had been satisfactory in his hands.

DR. L. H. DUNNING of Indianapolis remarked that the character of the suppurative products encountered by the surgeon called for different lines of procedures. In the cases described by the essayist, in which the pus accumulations were exceedingly large, extending as high as the umbilicus, fixed, and extending down into the vagina, it had been his practice for the last ten years, and he saw no reason to change it, to do vaginal section. In such instances where vaginal hysterectomy was done it was exceedingly difficult, if not impossible, to remove the pus-sac. He had operated in fifty cases of the kind described by vaginal incision. Of this number, four patients returned for subsequent operation. All but one of them had made primary recoveries.

DR. B. SHERWOOD-DUNN of Boston believes the perfection of technic of hysterectomy by the vaginal route exceeds in difficulty that by the abdomen to a great degree. The complications following the vaginal route exceeded those of the abdominal method. The danger to the uterus, the bowel, and post-operative hemorrhage were very much greater by the vaginal than they were by the abdominal route. He restricted vaginal hysterectomy to a few selected cases where he was fearful of death of his patients by the suprapubic route. The vaginal operation was difficult, and in many instances it had to be followed by a second operative procedure through the abdominal wall.

DR. W. E. B. DAVIS of Birmingham holds that vaginal incision and drainage has a large field. There was a great deal of difference between operating upon old gonorrheal cases and upon fresh ones. Unquestionably all of the cases following the puerperal state, where the surgeon can place his finger upon the side or behind the uterus, could be dealt with better by the vaginal route. The surgeon made a mistake when he opened the abdomen to deal with this class of cases, when vaginal incision and drainage was such a simple procedure. While a few patients would return for secondary operations, the surgeon should be willing to operate several times, if necessary, to save important organs.

DR. C. A. L. REED of Cincinnati formerly resorted to the vaginal route, and, after trying it carefully and conscientiously in many cases, he had practically abandoned it and had returned to the abdominal incision. He had, however, a class of cases in which hysterectomy was a very important concomitant in the course of treatment, but even in these he does not remove the uterus per vaginam.

The paper was further discussed by Drs. A. B. Miller, of Syracuse, and J. Henry Carstens of Detroit.

AFTERNOON SESSION.

DR. D. TOD GILLIAM of Columbus, Ohio, contributed a paper, entitled

OPERATIVE TECHNIC FOR INTRALIGAMENTOUS OVARIAN CYSTOMA.

Prior to the enucleation method of Miner the surgical treatment of these cases was crude and incomplete. Miner's method marked a new epoch and will ever remain the foundation principle of their surgical treatment. It was, however, attended with so much difficulty and danger as to greatly abridge its usefulness. The chief danger was from hemorrhage, which was oftentimes fearful and not infrequently fatal. Other, and by no means unimportant, dangers came from injuries to important

pelvic structures while conducting a hurried and blind dissection. There is a crying need for something better. The essential factors of the ideal operation are: (1) Tapping, to reduce the volume of the cyst and to open the way for hemostasis and enucleation; (2) ligating the supply-vessels to control hemorrhage; (3) enucleation along the line of cleavage to insure easy, rapid and safe dissection. This technic was foreshadowed in a case which the essayist operated on October 30, 1894. Here he gained his first knowledge of the line of cleavage for intraligamentous cyst and reported it to the Columbus Academy of Medicine. In 1896 Kelly announced the line of cleavage for intraligamentous uterine fibroid. Hall (in 1897) was the first to combine all the essential factors of the ideal operation. Hall's method, however, included hysterectomy. The method of the essayist without hysterectomy is as follows: First tap the cyst and drain off its contents; then ligate the ovarian artery near the pelvic wall and place a clamp between the cyst wall and the uterus. Select a point as low down on the anterior wall as practicable, and with a pair of forceps lift up the capsule and make a small opening. Insinuate a finger and sweep it around, separating the cyst from its matrix at the base. Now turn the finger upward and work in the direction of least resistance, slitting the capsule as you go. This will indicate the line of cleavage and will generally run upward and outward diagonally across the face of the tumor. Now introduce the hand and strip off the capsule from below upward, following the line of cleavage. Enlarge the opening by making an incision parallel to the capsular margin; seize the cyst and roll it out of its bed, stripping it from the posterior capsular wall. Trim and suture as in other cases.

GENERAL CONSIDERATIONS ON SEPTIC INFECTION OF OVARIAN CYSTS.

Dr. Charles Greene Cumston of Boston read this paper. Inoculation experiments had shown that if the liquid contents of an ovarian cyst were not contaminated by bacteria they would remain aseptic and would undergo no change. But if, on the contrary, microbes attacked a cyst and entered it, its contents would serve as excellent culture-media and symptoms of infection would soon appear. But the human organism would take on the offensive and would react against the bacteria which had infected the cyst; leucocytes come from the walls of the vessels and attack the invading microbes, and thus we have the transformation into pus of the liquid contents.

There were two kinds of septic infection of ovarian cysts, namely, pathogenic infection and saprophytic infection. Pathogenic and saprophytic organisms often enter ovarian cysts through a puncture, incision, and drainage track. As puncture is discarded in a great number of instances by the majority of the profession, the patient contains the agent of the septic process under consideration. The germs do not come from without, but from the interior of the organism, and it may be called a true auto-infection, which takes place in one of three ways: (1) By means of the blood, in which case the infection is either direct, produced by phlebitis, which extends up to the cyst, or it may be indirect, in which case the infective elements are carried in the general circulation into the tumor by means of its pedicle; (2) infection may take place by the lymphatics, in which case the lymphatic channels act as the contaminating canals and allow a direct introduction of the germs into the interior of the cyst up its hilum; (3) infection through adhesions which are plentifully supplied in new-formed vessels which are intimately connected with those in the walls of the cysts, and thus allow an easy transportation of the bacteria.

After giving at considerable length the symptoms of ovarian cysts and dwelling upon the diagnosis and differential diagnosis, the author dealt with their operative treatment. Operation for the removal of ovarian cysts which are the seat of septic infection may be divided into four stages: (1) Incision of the abdomen; (2) the breaking up of the adhesions and ligation of blood-vessels which they may contain, and then the pus may be removed by trocar and not with the knife, because if the cyst is incised pus will immediately flow out and the wound will very likely become infected by the septic material. The third step in the operation is the extraction of the cyst through the wound, and in doing this the surgeon should be careful to avoid infecting the abdominal incision at the time he is drawing the pocket through, but this complication may be easily avoided if aseptic gauze sponges are tightly packed around and inside the line of incision. Next comes the ligation of the pedicle and its section, after which it is dropped into the abdomen. The fourth step of the operation consists in the cleansing of the peritoneum, which should be done with great care, especially when the operative field has run any chance of infection. If this has occurred, free irrigation of the peritoneum is proper, but it should be done with care and the liquid employed should be a warm normal salt solution. Care should be taken to limit the irrigation to the subumbilical portion of the peritoneal cavity and a back flow of the liquid toward the diaphragm should be prevented by having the operating-table perfectly flat and the thorax slightly raised.

Dr. Henry Howitt of Guelph, Ontario, read a paper, entitled

A SECOND CONTRIBUTION TO THE SURGICAL TREATMENT OF INTUSSUSCEPTION IN INFANTS, WITH CASES.

In the paper the term infant was restricted to those under one year of age. After briefly describing the different varieties of intussusception that occur at any period of life, and also referring to particulars in regard to statistics, modes of growth, length of bowel involved, and the severity of the attack in the varieties, he stated that in the infant we have only the acute forms with which to deal in practice, nay, possibly only the ileocolic, which all authorities agree to be the most acute and rapid variety of invagination. It is, he stated, the ileocecal form plus the valve distended and its lumen occluded by the swollen and edematous invaginated portion of ileum which, owing to the tight constriction at the neck by the valve, in a manner resembles a well-hammered boiler-rivet

that no evenly distributed pressure from within can force out.

The author believes that many instances of the trouble occur in infants, leading invariably to death without the true nature of the malady being recognized by the attendant; and that when the facts having reference to this variety of intussusception become generally known, fewer deaths will be recorded of certain bowel affections and more lives saved by surgical means. He has seen seven cases, six of them almost within the past five years, or since his attention was drawn to the subject. Six were in male children; all came from a district the population of which is under 12,000. He has operated successfully on four, all of whom were under six months of age. A fellow practitioner lost one owing to an accident during operation. In one case the friends refused operation and death resulted, and one died shortly after the onset before anything could be done.

The symptoms of iliocolic intussusception were fully dwelt upon. In regard to its diagnosis, the speaker emphasized the importance of the history of the onset, and stated that without it the attendant may be likened to a ship in a storm without helm or compass. In fact, the nature of the onset might suffice to make a diagnosis. The detection of a tumor in the course of the colon left no room for doubt.

The condition of this form of intussusception is such as to preclude the hope of recovery by any method short of operative. No time should be lost in trying either bowel inflation or injection of fluids. They can do no good. His method of operating is as follows: He maintains the temperature of the child by suitable applications to extremities and body during operation. Rigid aseptic preparations and precautions should be carried out. A median, three-inch incision, avoiding the high-placed bladder, is made; the small intestines are eventrated as rapidly as possible, and protected with gauze, which is irrigated with water of suitable temperature. The evisceration allows the obstructed portion of intestine to be brought into view. When, as is generally the case, the invagination has reached the transverse colon, the surgeon cannot bring it out of the wound till the part of the large bowel implicated is disinvaginated. This is accomplished by making pressure on the apex of the intussusceptum while the intussuscipiens is pulled in the opposite direction. It is done by grasping the colon close to the apex with the hand and following it up the bowel step by step till the colon and cecum are free. The mass is now lifted out of the incision. Then comes the most difficult point —the reduction of the invaginated portion of ileum. The part is grasped in the hand and firmly pressed for a few minutes; then pressure is made with the thumbs on the apex, while the fingers surround and support the outer orifice of the ileocecal valve. The method resembles that used in paraphimosis, only the large bowel covers the part from view.

Before returning the intestines to the abdominal cavity the contents of which have accumulated in the ileum above are forced through the affected part into the colon; this proves that the difficulty has been effectually overcome and ensures an early movement of the bowels. Drainage is not necessary. The omentum is spread over the intestines to prevent adhesion of bowel to the line of incision. The dressing is covered with oiled silk, the edges of which are sealed with collodion to prevent urine reaching the cut.

DR. REED said his experience was restricted to a single case of intussusception in infants. The child was operated on in extremis and died within the first five hours following the operation. With early interference the outcome might have been different.

DR. PRICE said the cases reported are a beautiful demonstration of what can be accomplished by good judgment, great diagnostic skill, and early surgical interference.

DR. W. E. B. DAVIS thought it unusual for one man to have so many cases of invagination in infants. He had only met with one case, and this occurred ten days ago, the child, a male, being eight-months old.

DR. HALL recalled half a dozen cases of intestinal obstruction in infants in sixteen years general practice that had died. He believed the invagination is overlooked in the majority of instances.

DR. JOHN M. DUFF believed intussusception in infants occurs more frequently than is generally supposed. He had held *post-mortems* on several cases where the diagnosis was doubtful, but intestinal obstruction was found. He had seen two cases within the past year; in one operation was refused, and the child died. At the autopsy intussusception was found. The other patient was operated on after peritonitis had set in, and death followed.

DR. CUMSTON had seen four cases of invagination in children.

FIRST DAY—EVENING SESSION.

DR. JOSEPH PRICE of Philadelphia, read a paper with the caption

NURSING IN ABDOMINAL SURGERY.

The time had passed when any question was raised by intelligent and experienced members of the profession as to the value of the trained nurse. Nurse-training schools had become important institutions not only to young women who with a creditable ambition entered them to fit themselves for the profession of nurse, but to the physician; for the physician, whether in general or special practice, knew the value of the trained nurse, understood the close and vital relation she held to his patient; how much her care and quick intelligence of needs did to relieve his anxiety and promote the welfare of his patients. The training of these schools should be specially and simply directed to fit pupils for the duties of nurses. These duties in all their details, and all the steps in the training essential to discharge them faithfully and intelligently, should be definitely, orderly, and clearly outlined by teachers of thorough experience. Those desiring to become nurses should commence their work early, while young, studious, and ambitious; while their habits are not so fixed as to make a change difficult, if not impossible. Too much had always been expected of nurses in private nursing. Nursing through twenty-four consecutive hours was too much to require of human endurance

and resulted in neglect of the patient. Systematically trained special nurses were usually bright, cheerful, interested, and spirited; were alive to the importance of their work; cared for and infused into their patient some of their own animation. The untrained nurse, on the other hand, was meddlesome and dangerous. Young, healthy, unmarried women were to be preferred, not widows or grasswidows, great-aunts, or grandmothers.

Second Day—September 21st.

Morning Session.

Dr. W. J. Asdale of Pittsburg read a paper in which he reported an interesting case of extra-uterine pregnancy, with mature fetus, and exhibited the specimen. The skeletal remains were borne seventeen years over the completion of gestation term, and the condition was eventually complicated by an ovarian cyst. No operation was performed. The patient died. At the autopsy a monocyst of the right ovary of large size was emptied and withdrawn. One of the long bones of a fetal skeleton was found in the pelvis free; from high in the left hypochondrium underlying the left lower ribs and just beneath the diaphragm the remains were found—skeletal—of a fetal body, disarticulated and closely packed together. The bones were invested by the intestine, a portion of which was cut away in the removal. The fetal soft parts had, at the time of autopsy, almost entirely disappeared. Records of successful operations undertaken for the removal of long-retained fetal remains were so rare as yet to be exceptional, and how much more doubtful surely would be the result of operative interference in such a complicated case as this.

Remarks on Primitive Amenorrhea, with Report of a Case and Presentation of Accompanying Pathological Specimen.

Dr. Walter B. Chase of Brooklyn read a paper on this subject in which he said that the essential fact in the sexual life of women was the predominating control of ovarian influence, and the central fact in the pathology of woman's sexual life was due in a large degree to changes or perversion of function or structure of the ovary. While ovarian function was not the single influence which swayed woman's existence, the absence of it would dethrone her womanhood. The commonly accepted theory concerning the functional activity of woman's sexual life was that menstruation marked the commencement of ovulation, and that in its ordinary manifestations they were, in point of time, coincident. The experience of all observers doubtless furnished exceptions to the common law, but these exceptions served rather to confirm than abrogate it. Among these variations or absence of physiological processes, amenorrhea in some of its forms was of common frequency. An intelligent and comprehensive distinction in amenorrhea embraced a difference between those cases which were congenital or acquired. In the former, emansio mensium or primitive amenorrhea, the causes were congenital and chiefly physical, while in the latter, suppressio mensium or acquired amenorrhea, the causes were functional, or largely so. In the first class menstruation has never been present; in the second class the function once present is arrested. Primitive amenorrhea may result from congenital deficiency or imperfect development as follows: absence or imperfect development of ovaries and uterus; degeneration of the ovaries, cystic or otherwise; the formation and development of benign or malignant tumors of the ovaries sufficient to preclude or abolish their function.

Report of Case.—Mrs. B., aged twenty-four; a woman of refinement and fine physical development; had been married about two years; was sterile, and had never menstruated. She gave an intelligent history of having had all of the symptoms which usually accompany menstruation since the age of puberty, except the appearance of the menstrual flow, commencing at about eighteen years. The symptoms of discomfort developed with perfect regularity every twenty-eight days, with a history of increasing pain and nervous excitability, until during the eighteen months previous to his having seen her the pain had become unbearable and nervous perturbation such that she and her friends feared insanity. The one subjective symptom which gave rise to her fears of mental disturbance was severe headache and pressure felt at the vertex, which was present for several days at each menstrual molimen. During a year or more she had become conscious of a gradual enlargement of the abdomen, and could herself easily define an abdominal tumor. She entered the service of Dr. Chase at the Bushwick Hospital, and a careful study was made of her case by the consulting gynecologist and himself. The patient was desirous of an operation.

Operation was performed. The first tumor removed was a dermoid and had no pedicle, but was closely adherent to the uterus and the right broad ligament. The second tumor was a suppurating multilocular cyst of the left ovary.

The report of the pathologist was: (1) that the dermoid had usurped the place and destroyed the function of the right ovary. (2) In one of the cyst walls of the multilocular ovarian cyst was found a shrunken ovary the size of a large lima bean, and within this ovarian stroma was found a corpus luteum spurium. To the presence of this ovarian stroma was due the womanly development, with ovulation, and the futile effort of menstruation and its consequent suffering. (3) It demonstrates the possibility of ovulation without menstruation. (4) It leaves us in doubt whether the absence of the Fallopian tubes was primary or secondary to the grave disease of the ovaries, with the possibility that they were congenitally absent. (5) It presents the rare and exceptional condition of a perfectly developed woman who had an ovary and uterus, who ovulated, was sterile, and never menstruated, and yet was ruined in health by Nature's effort to establish an impossible normal function.

The remainder of the session was devoted to the presentation and discussion of pathological specimens. Specimens were exhibited by Drs. John B. Deaver, X. O. Werder, Rufus B. Hall, and Wm. H. Humiston.

Afternoon Session.

President's Address.

This was delivered by Dr. Charles A. L. Reed of

Cincinnati, Ohio. He selected for his subject

THE EVOLUTION OF SPECIALISM.

He said that modern specialism in medicine dates from the period when the French schools, in the early decades of this century, took up seriously the question of pathological anatomy. This was the physical basis upon which the work of division began. The obstetrical art was as old as the function of reproduction, although the latter ages had witnessed its present refinements. It had been said that obstetrics married surgery, and that the fruit of the union was bright-eyed gynecology. The accouchement probably occurred at the time Recamier invented the speculum in 1801. While surgery had its first rational development in the United States in 1809 under the masterly hand of the immortal McDowell, everything from that day to this was essentially contemporaneous history, in which occurred conspicuously many of the proudest American names. Specialism became a verity in response to natural laws, which even to-day determined its destiny. There was not a day but that the general medical profession became enriched in resource and potentiality by the accretions derived from specialism. Each specialty, however assiduously cultivated, remained an integral part of the great general profession, the masters of which must ever stand as our ideals. All specialists to-day were primarily the products of general medical culture.

THIRD DAY—SEPTEMBER 22ND.

MORNING SESSION.

DR. D. TOD GILLIAM of Columbus, Ohio, read a paper on the

TREATMENT OF GRANULAR EROSIONS OF THE CERVIX,

and reported three cases which he had treated successfully by ligation of the cervical vessels.

DR. B. SHERWOOD DUNN of Boston followed with a contribution on

THE RELATION OF NERVOUS AFFECTIONS TO DISEASES OF THE FEMALE PELVIC ORGANS.

He limited his remarks to the great neuroses of neurasthenia, hysteria, and insanity. He was totally opposed to any operative procedure, except where pathological conditions were demonstrable. He had no confidence in operations upon healthy organs for the cure of any neurotic condition, and believed that such were now generally condemned by the profession. He, however, looks upon the position taken by some neurologists, that there is no relation of cause and effect between the various neuroses and psychoses and disease of the female pelvic organs as being as extreme and condemnatory as the advocacy of the removal of normal organs in the female pelvis for the cure of nervous diseases, by some ill-advised persons calling themselves gynecologists. In operating upon diseased conditions in the peivis, the gynecologist did not expect to remove the symptoms of the neuroses, but only those symptoms properly belonging to the pelvic disease itself. But strange and disappointing as it might seem to be to some of the critics, when those pathological pelvic conditions were removed or corrected, the nervous system relieved from the source of unceasing irritation, gradually returned to its normal poise, and the patient was cured of her neuroses as well as her pelvic disease.

DR. WM. H. HUMISTON of Cleveland, Ohio, read a paper on the

GRAVER FORMS OF NERVOUS DISTURBANCES DUE TO ORGANIC CHANGES IN THE GENITAL ORGANS.

In the last five years of his work the essayist had never operated upon a case in which the corelation between the diseased pelvic organs and the nervous symptoms were not clearly defined before an opinion from a neurologist relieved him of a doubt of a nerve or brain lesion, with one exception. He reported six cases in which great relief, in some cures, followed operative interference. The first case was one of insanity; the second, melancholia; the third, neurasthenia; the fourth, insanity; fifth, hystero-epilepsy, and the sixth, hysteria. The cases were reported with the hope that some effort would be made to secure for women confined in county and State institutions for the insane such surgical measures which would, in a large proportion of cases, be a curative means for their mental ailment, and which must, in a vastly greater proportion at least, improve their condition, both mentally and physically.

DR. RUFUS B. HALL of Cincinnati read a paper on

ALBUMINURIA COMPLICATING GYNECOLOGICAL OPERATIONS.

He referred first to the conditions predisposing to this complication. He urged careful examination of the urine preceding operation so as to determine, if possible, the presence of nephritis or other causes leading to suppression. The most common cause is a preexisting nephritis but unfortunately in granular nephritis, a most careful examination of the urine may fail to show the presence of the disease. One of these patients after the operation may have suppression followed by coma and death. He said there might also be suppression following operation in a patient with a fatty heart or with atheromatous arteries. It is of the greatest importance to have the patient thoroughly prepared for operation. If there is the least indication of preexisting nephritis, he advises chloroform as an anesthetic, regardless of the age of the patient. In his early operative work he used ether almost exclusively. He cited 110 sections in which ether was given.

In 33 cases there was a trace of albumin in the urine during the first 24 hours. In 10 cases there was partial or complete suppression and 2 of the patients died in coma. During the time he used ether, he operated on 7 patients known to have nephritis. They were given chloroform. These cases are included in 500 sections in which that drug was the anesthetic used. Eighty-five of this number showed a trace of albumin in the urine during the first 24 hours after the operation. Ten patients had suppression and 4 died of uremic coma. All the patients who were known to have kidney disease were given chloroform. There were thirty-five of these, and the deaths in the chloroform list were from this number. To avoid the dangers from the use of chloroform, he urged that its administration

be only entrusted to an expert in its use. He closed his paper with a résumé of the preliminary treatment he accords every patient about to be subjected to a section; of the manner in which he conducts his operations, and of the measures he employs if albuminuria occurs following operation.

Afternoon Session.

Dr. X. O. Werder of Pittsburg gave the clinical observations of more than 100 abdominal sections for ovarian tumors.

Dr. Frederick Blume of Allegheny, Pa., reported a case of double uterus and vagina with pregnancy in one horn, in which he excised the vaginal septum.

The election of officers for the ensuing year resulted as follows: President, Dr. Edward J. Ill of Newark, N. J.; first vice-president, Dr. Edwin Ricketts of Cincinnati; second vice-president, Dr. A. B. Miller of Syracuse, N. Y.; secretary, Dr. Wm. Warren Potter of Buffalo, re-elected; treasurer, Dr. X. O. Werder of Pittsburg, re-elected. Executive Council: Drs. A. Vander Veer, L. S. McMurtry, W. E. B. Davis, John M. Duff, L. H. Dunning, and Walter B. Chase. Indianapolis, Indiana, was selected as the place for holding the next meeting, the time of which was left to the Executive Council.

REVIEWS.

A Text-Book on Surgery. By John A. Wyeth, M.D., Professor of Surgery in the New York Polyclinic Medical School and Hospital. Third edition. New York: D. Appleton & Company, 1898.

The practical character of this text-book is the feature that has commended it to the favorable consideration of the profession. This third edition has enabled the author to bring the work up to date while retaining its practical character. Many of the chapters have been re-written and enlarged so that the work exceeds the former edition by 112 pages. Throughout all the editions the author has shown his loyalty to American surgery, and due credit has been given to Americans for their contributions to the science and to the advances which have been made in surgical work. As has been stated, the work is severely practical and mirrors the methods and treatment of the author; the etiology and pathology of disease are presented only in their most general aspects. The illustrations are very abundant, and for the most part are clear and instructive. Chapters XIV. and XV. on Aneurisms and Ligation of Arteries are especially clear—perhaps the best in the book. The author's operations for bloodless amputation at the hip- and shoulder-joints are clearly and elaborately described, and amply illustrated.

In spite of the general excellence of the work there are a few points in which the author has laid himself open to criticism. The differences between asepsis and antisepsis are not clearly defined although the general impression is that the author leans to antisepsis. The classification of pus into "surgical" and "laboratory" pus is most crude. It has always been held, and correctly so, that the margin of erysipelas is very abrupt and not as herein stated, as fading gradually into the surrounding healthy skin. What the author intends to convey by the term "aseptic poultice," as recommended in the treatment of lymphangitis is rather obscure, and the statement that tubercular adenitis is a form of lymphangitis is open to question. Priority for the method of tendoplasty for paralysis belongs to Nicolodain (1882), and not to Dr. Parrish (1892). We have always been taught that the cells lining the interior of the hydrocele sac are endothelial not epithelial as mentioned on page 836.

Numerous inaccuracies of like nature are noticeable throughout the work. The general appearance of the book is attractive and the publishers have done their part well.

Tropical Diseases; a Manual of the Diseases of Warm Climates. By Patrick Manson, M.D., LL.D. (Aberd.). New York: William Wood & Company, 1898.

The author's wide experience in this department of medicine has enabled him to talk authoritatively on the subjects which are contained in this book. After an introduction dealing with the etiology and methods of propagation of the various tropical diseases, he begins the section on fevers with a consideration of the subject of malaria. Dr. Manson is well known by his writings on this subject and in this work he refers at length to his theory of the introduction of the plasmodium into the human system. Inasmuch as he claims no more than a logical conclusion from definite data, and since recently Koch of Berlin has come to the same conclusion in reference to the mosquito being the factor of the propagation of the malarial parasite, we are inclined to believe that his theory is strongly substantiated. He lucidly shows how the malarial parasite may leave the human body affording an opportunity for its extracorporeal existence; he describes its extracorporeal history and how it enters the human body. The author is extremely modest and honest in stating his deductions as to the mosquito hypothesis, as is demonstrated by his own words: "I do not maintain that this mosquito hypothesis has as yet been thoroughly proved, but I do maintain that it is so probable, and of a character so important, from both both a scientific and practical point of view, that every effort should be made to establish or confute it."

The article on malaria is one of the best in the book and contains a vast amount of information.

Section II. deals with general diseases of undetermined nature, such as beriberi, epidemic dropsy, and negro lethargy or sleeping sickness.

Section III. is devoted to the abdominal diseases, cholera, dysentery, abscess of the liver, and some of the diseases common to specific districts in the tropics, such as infantile biliary cirrhosis, occurring chiefly in Calcutta and affecting rather Hindu than Mohammedan children, and "ponos," an analogous disease endemic in the islands of Spezzia, Ilydra, and others in the Grecian Archipelago.

The fourth section is given to the description of "infective granulomatous diseases," such as leprosy, yaws, etc.

Section V. is one of the most important in the book and deals with "the animal parasites and associated diseases." The author considers in detail the diseases produced by the parasites which are chiefly confined to the circulation and to the lymphatics, these parasites being chiefly the varieties of filaria and the *hematobia bilharzia*. He considers all the affections produced by the *filaria nocturna* such as elephantoid fever, lymph scrotum, chyluria, filarial orchitis, elephantiasis, and chylous dropsy of the tunica vaginalis and peritoneum. Endemic hematuria is considered in the article devoted to the consideration of the *hematobia bilharzia*.

The parasites confined to the connective tissue of the body and the affections produced by their presence there are next described in the chapter devoted to the guinea-worm (*filaria medinensis*). Next we find a consideration of endemic hemoptysis, due to the *parasite distoneum Ringeri*, which is confined to the lungs. The parasites of the liver and intestines are likewise considered.

The last two chapters are devoted to a description of the various skin diseases found in the tropics, some of which, such as Madura foot and dhobic itch, are caused by vegetable parasites, and to local diseases of uncertain nature.

The book contains, as will be seen from the above résumé, a large amount of matter. It is surprising that the author was able to condense all this matter in so compact a space without a sacrifice of clearness and accuracy of description. The book does not claim to be a complete treatise on tropical diseases but simply an introduction to this important department of medical science. As such it more than fulfils the requirements, and will serve the student as an accurate guide.

ATLAS OF LEGAL MEDICINE. By DR. E. VON HOFMANN, Professor of Legal Medicine and Director of the Medico-Legal Institute at Vienna. Authorized Translation from the German. Edited by FREDERICK PETERSON, M.D., Clinical Professor of Mental Diseases in the Woman's Medical College, New York; Chief of Clinic, Nervous Department, College of Physicians and Surgeons, New York. Assisted by ALOYSIUS O. J. KELLY, M.D., Instructor in Physical Diagnosis, University of Pennsylvania; Adjunct Professor of Pathology, Philadelphia Polyclinic. Philadelphia: W. B. Saunders, 1898.

THE publishers are to be congratulated in again putting before us one of Lehmann's superb atlases, and it is not at all surprising that these works have appeared in nine different languages, for until now the means of producing illustrations in colors or otherwise faithfully to represent normal or diseased conditions have not been entirely successful. A cursory glance at the Lehmann books is at once convincing that a new era has begun in this line.

The work before us comprises a large number of full-page plates, many of them in colors, and numerous smaller illustrations, representing common and rare conditions of pathologic and medico-legal interest. The text supplies simply a brief history of each case and the necessary data bearing upon the subject, the deductions in each case of suicidal or homicidal death being characteristic of the immense experience and logical mind of the late author.

The work is not only valuable to the expert in forensic medicine and the clinician but is indispensable to every worker in the autopsy-room and the pathologic laboratory. The editors have closely followed the original text and have done their part in an admirable manner. The book is published in the same convenient and handy size as the original and we can heartily recommend it and trust that it may reach the eyes of all interested in the subject.

THERAPEUTIC HINTS.

For Severe After-Pains.—

℞ Antipyrin . . . . . gr. iiss
Quininæ sulphat. . . . . gr. iii.

M. Ft. chart., No. I. Sig. One such powder every three hours while pains remain severe. If the condition of the patient should contraindicate antipyrin, the following powder may be substituted:

℞ Pulvis opii } aa . . . . . gr. ½.
Camphoræ }

M. Ft. chart., No. I. Sig. One powder every hour until relief is obtained.

Sedative Mixture in the Treatment of Uterine Fibroids.—

℞ Sodii bromidi }
Ammonii bromidi } aa . . gr. lxxx
Strontii bromidi }
Aq. dest. . . . . ℥ viii.

M. Sig. Two to three tablespoonfuls daily.

For Intermittent Fever when it does not yield to treatment by quinin alone, BACELLI recommends the following combination with arsenic and iron:

℞ Quininæ sulphat. . . . . ℥ i
Ferri et potassii tartrat. . . . ℥ iiss
Acidi arseniosi . . . . gr. i ⅔
Aq. dest. . . . . ℥ x.

M. Sig. On the day following the fever, one tablespoonful every hour; on the next day every three hours, and so on in this manner.

Powder for a Suppurating Surface.—

℞ Iodoformi }
Salol }
Bismuthi subnitrat. }
Pulv. carbonis } aa . . . ℥ ii.
Pulv. cinchonæ }
Pulv. benzoini }

M. Sig. For external application.

For Sick Headache.—

℞ Ol. caryophylli . . . . *m.* xl
Ol. cajaputi . . . . *m.* lxxx
Sodii bicarb. . . . . gr. lxxx
Chloroformi . . . . gtt. lxxx
Tinct. cardamomi comp. . q. s. ad. ℥ ii.

M. Sig. One teaspoonful three times a day.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIII. NEW YORK, SATURDAY, OCTOBER 8, 1898. No. 15.

ORIGINAL ARTICLES.

ARE COMPLETE CASTRATES CAPABLE OF PROCREATION?[1]

BY F. R. STURGIS, M.D.,
OF NEW YORK.

THE subject that I have selected for your consideration may perhaps cause a smile on the ground that it is one of scientific curiosity rather than of practical worth; but a moment's reflection will, I think, show you that it is of value, if not from the purely surgical side, at least from the standpoint of forensic medicine.

Scattered over the pages of medical literature are instances in which the legitimacy of a child has been called into question on account of a suspicion as to its paternity, and it oftentimes becomes of importance not only for the good name of both woman and child, but also sometimes for the inheritance of estates, that this question should be solved. While we admit that the absence of testes in the male throws a strong doubt upon the legitimacy of the child, I myself believe that there is some evidence within certain limits to support the view that a man who is deficient in both of his testes may yet be the father of his child, and I ask your consideration, first, in order to detail the experiments bearing upon this point, which have been made on animals, and, second, in adopting the deductive method of reasoning to take up those cases in which men who have become eunuchs have yet been reputed to be fathers of children.

The possibility that entirely castrated animals may within certain limits be capable of procreation is as old as the days of Varro, who, in his book "De re Rustica," stated that he had "found something written of these animals (to wit, bulls) that is noteworthy; that even when the testes are abstracted, if they are put at once to cow they are capable of procreation." (Liber ii, 1619.) Aristotle, also, in his "History of Animals," Book iii, says: "And it has happened that a bull has begotten young if admitted to the female immediately after castration." Whatever we may think of the scientific knowledge of the ancients, there is no reason to doubt the accuracy of their statements; they were acute observers, and so far as their eyes were of any use they knew what they were talking about.

Passing on from the Greek and Roman writers to the Arabian school of medicine, I have not been able to trace any evidence whatever that this subject was studied, possibly for the reason that the Arabians, the Saracens, and the Moors were not prone to practise castration either upon man or beast.

The next mention of this subject which I can find is contained in the *American Intelligencer*, for the year 1838, in an article, entitled "Note on the Power of Procreating after Castration": "A question has been asked, whether, if a man be castrated after the age of puberty he may not be able for a few days after the operation to impregnate with the sperm contained in the seminal ducts and vesicles. . . . This has been generally doubted, both as regards animals and man, but there is no question of the fact in the case of the former. . . . We have recently obtained the following information on this point: A valued friend of the editor (Dr. Pue), who practised in Baltimore, has furnished him with many facts of the kind which fell under his own observation or that of his friends. In one case a boar was observed on one side of a hedge in a field of his farm striving to get at some sows in heat on the other side. The boar was castrated and no inconvenience being apprehended he was turned loose into the field with the sows. In five minutes after the operation he had intercourse with one of the sows and subsequently with others. The first sow brought forth a litter, the young marked like the sire. None of the others was impregnated.

"In another case, after a horse had been castrated, it was recollected that the yard had not been washed, which it seems is looked upon as advisable. To save trouble it was suggested that the same effect might be produced by putting him to a mare then in the stable and in heat. This was done and in due time the mare brought forth a foal unequivocally the result of this sexual union.

"A gentleman who is a great breeder of horses in Saratoga County, New York (Mr. Walton Hamilton), informed the editor's friend, Nicholas P. Frist, Esq., United States Consul at Havana, that he had known several instances of impregnation after castration."

In the same journal the same year is another article on "The Power of Procreating after Castra-

[1] Read before the American Association of Genito-Urinary Surgeons, June, 1898.

tion," which contains a letter addressed to Professor Dunglison by Joseph Warrington, Esq., in which he says: "In looking over a recent number of the *American Library and Intelligencer* I perceived some notices of occasional instances of the capability in animals to procreate after castration. Although contrary to the general impression that this function is immediately destroyed by the removal of the testes, I am prepared to credit the statement by an observation which I made several years since. A sow in heat had left the herd of a neighboring farm, and visited that on which I then resided, in search of a boar, which having, as was supposed, served the purpose of impregnating all the sows of that and the adjoining farms had been fully castrated two days before this visit. With nearly his accustomed energy, however, he covered the sow, which, without further coition, ceased to be in heat, and in due time produced a litter of pigs. The barrow from that period never evinced either inclination or ability for sexual intercourse."

In similar statements which have been made not only by ancient but by modern authors, it is noticeable that no particular period is assigned within which the fertility of the procreating powers is retained; and while it would seem very probable that the power is not entirely lost for some little while after the mutilation has taken place, we are unable to say up to what time that power exists.

The next series of experiments which I have to present are those of Obolonsky,[1] who experimented upon two dogs, in both of which animals the testes were entirely removed. In the first dog the secretion of the vesiculæ seminales was examined *seven days* after castration, when spermatozoa were found in great quantity, but without motion. On the addition of a weak solution of bicarbonate of soda, however, the movement of the spermatozoa became quite lively and they appeared to be perfectly normal. In this dog the external wound of operation had not entirely healed. In the second, the wound had entirely healed, the examination being made *thirty-one days* after the operation. The contents of the vesiculæ seminales showed abundant spermatozoa, but less in quantity than in the first case. At first they were without motion, but upon adding a weak solution of bicarbonate of soda they became quite lively. So far as the microscopic appearances went they were perfectly normal, and Obolonsky is of the opinion that had the dog at that time indulged in coitus he would, everything else being equal, have proved fruitful.

The next series of experiments were those made by Masuraca.[1] His experiments were nineteen in number, made upon fourteen animals, seven of which were dogs, four cats, and three guinea-pigs. The technic consisted in removal of the testes by a transverse incision into the scrotum, and after removal the cord and the vasa deferentia were ligated and the wound dressed antiseptically. The only exception was in the case of the guinea-pigs, in whom, the testes being in the belly, no ligation was made; otherwise, the procedure was the same as in the other cases. Death was induced by hanging. In all the subjects of the experiments spermatozoa were found in the epididymis. Of the seven dogs that were experimented on, the first was killed twenty-four hours after the operation. In the vasa deferentia normal spermatozoa were found, few in number and endowed with motion. The second dog was also killed twenty four hours after the operation. In it abundant normal spermatozoa were found which were for the most part endowed with movement. The third dog was killed three days after the operation. In it normal spermatozoa were found, of medium quantity and without motion. It is worthy of note that in the hanging of this dog a white milky drop came from the urethra which, on being examined, contained no spermatozoa whatever. The fourth dog was killed sixty-four hours after the operation. Abundant spermatozoa were found, which were normal in appearance and endowed with motion. In this dog, also, during the process of hanging, a white drop came from the urethra in which no spermatozoa were found. The fifth dog was hanged four days after the operation. In it a moderate number of normal spermatozoa were found, but they were all motionless. In the sixth, the animal was killed five days after the operation. Only a few spermatozoa were found, but these few were normal in appearance and endowed with feeble movement. The seventh dog was killed seven days after the operation. In this animal the vasa deferentia were empty. Only one single body which looked like a spermatozoon was found which was endowed with a head. The body was thickened; it was crumpled in appearance and seemed to have become granular.

Of the cats, which were four in number, one was killed four days after the operation. During the hanging the bladder was emptied and a milk-white drop exuded from the urethra, which, upon examination, was found to be full of normal spermatozoa. The hanging was interrupted and the animal resuscitated. This same animal was hanged upon the next day, five days after the operation. Abundant spermatozoa were found in the vasa deferentia and these

[1] *Vierteljahrschrift für Gerichtlichen Medezin*, N. F. Bd. 48, p. 362, 1888.

[1] "Sopra un Importante Questione Relative alla Castrazione."

were for the most part endowed with motion. The second cat was hanged six days after the operation. In this animal only few spermatozoa were found, some of which were endowed with feeble motion. The third cat was despatched seven days after the operation. In this animal the spermatozoa were present in large quantities, but they were not endowed with motion. The fourth cat was hanged twenty-five days after the operation and in this animal no spermatozoa were found, nor were there any bodies which looked at all like spermatozoa.

Of the three guinea-pigs, the first one was killed four days after the operation. In the vasa deferentia of this animal abundant spermatozoa were found but they were all straight and motionless. The second guinea-pig was hanged six days after the operation. During the hanging a large milk-white drop escaped from the urethra, which, upon examination, was found to contain numerous cellular elements of various size and abundant spermatozoa, which were straight and not endowed with motion. In the case of this animal, the hanging was interrupted; it was resuscitated and was used again for the third experiment, when it was killed eight days after the operation. During suspension many milk-white drops exuded from the urethra, which were found to contain an abundant number of cells with spermatozoa, having the general appearance that was present in this same animal two days before. These spermatozoa were not endowed with motion. Although an effort was made to resuscitate this animal, it was unsuccessful. The third guinea-pig was used for an extended series of experiments, being hanged no less than four times before it was finally despatched. The first time it was hanged ten days after the operation and during suspension an abundant milky secretion exuded from the urethra. This secretion was found to contain numerous cellular elements and an abundant quantity of straight and motionless spermatozoa. Some of these spermatozoa were seen to have their tails curled and to be slightly thicker than normal. As noted above, this animal was cut down before it was completely dead and was resuscitated without any trouble.

The fifth experiment (third guinea-pig) was made fourteen days after the operation. As before, the usual drop appeared at the urethra and this drop revealed, upon examination, an abundant number of straight, motionless spermatozoa, with clear outlines. This animal was again resuscitated and used as the subject for the sixth experiment. It was again suspended seventeen days after the operation. The usual urethral drop made its appearance, which, upon examination, showed granular degeneration of the epithelial cells, free fat globules, and some motionless straight spermatozoa. The same animal served as the subject for the seventh and final experiment, twenty days after castration. The usual urethral drop appeared during suspension, which, under the microscope, showed epithelial elements, no spermatozoa, and some white dodecahedral crystals which upon the addition of acetic acid took a crystalline form resembling a Latin cross (Boettcher's crystals?).

These experiments are interesting because so far as animals are concerned there seems to be a difference in the viability of the spermatozoa after complete castration. In the dogs, which were seven in number, and in whom seven separate experiments had been made, spermatozoa were found on the sixth day, few in number it is true and with feeble movement, but still spermatozoa, proving that the semen was more or less fruitful. On the seventh day we practically for the first time lose sight of the spermatozoa. The dog has now become sterile, as, of course, he would sooner or later become on the loss of his testes. With regard to the cats, there seems to be a wider limit. These cats were four in number, und upon these four, five experiments were made. Up to the end of the first seven days spermatozoa were abundant, but without motion.

It is to be regretted that in all these cases where spermatozoa, although present, were motionless, Obolonsky's experiment of adding a weak alkaline solution to the semen was not tried, as it is very possible that the spermatozoa would have become endowed with motion and the semen become practically a fertile fluid. Probably this takes place in the natural condition when the spermatozoa come in contact with the alkaline secretion of the uterus, and it is likely that the secretion of this organ is alkaline for the very purpose of securing the viability of the spermatozoa and the consequent fertility of the semen.

In the guinea-pigs we find a curious condition of affairs. Three of these animals were used for the purpose of experiment and on these three animals seven experiments were made, two upon one animal and four upon another. In these three animals, although the spermatozoa were fairly abundant up to the fourteenth day after the castration, in none of them was the spermatozoa found to be endowed with motion outside of the body; and in two experiments—the ones made upon the seventeenth and twentieth day after the operation—degenerative changes had taken place. In one—that is on the twenty-fifth day—the spermatozoa were entirely absent, and on the seventeenth day, although they were present, it is very evident that they were not normal, and probably not fertile.

Let us turn now from animals to man and note

what has been found in those individuals who have been castratedas regards the question of their fertility or sterility. Krugelstein, in Henke's *Zeitschrift der Staatsarzneikunde*, 1842, relates the case of a merchant who had both testes removed for some disease. The wound healed and he married. His wife became pregnant. In addition to this case others are noted, but as in many of them I have been unable to consult the originals, I have omitted doing anything further than report them by name. I refer to the cases of Cornelius Consentinus of Bohn; of Bellefontaine, of Zipans, and of Sanchez.

Sedillot, in his "Manuel Complet de Medecine Legale," borrows a case from Boyer, in which the latter was consulted by a man from whom he had at one time or another removed both testes for sarcocele. After recovery from the second operation he continued to cohabit with his wife, who became pregnant a short time afterward. The man, being somewhat disturbed, consulted M. Boyer, who in order not to "disturb the peace of the household," told the man that such a thing was quite possible, but added that it was his last child and if any others appeared he might be quite sure that they did not belong to him.

Krahmer[1] reports a case of a young peasant, twenty-two years of age, who performed self-castration with a razor. Both testes were entirely and thoroughly removed. Eleven to twelve days after the operation he had a seminal emission during his sleep. Unfortunately no examination was made for spermatozoa and it is only mentioned here as instancing the possibility of a seminal emission occurring twelve days after the operation of castration.

The last of all is the case which has been reported by Princeteau in the *Annales des Maladies des Organes Genito-Urinares* for 1890, taken from the "Proceedings of La Société d'Anatomie et de Physiologie de Bordeaux," in which the patient, a young man, had lost both testicles by castration from tuberculous disease and in whom upon examination no trace or fragments of these organs could be found. Notwithstanding this fact the young man frequently practised coition, and had ejaculation of a fluid containing spermatozoa, of which Princeteau showed some preparations.

Having now gone over all the cases, experimental as well as clinical, which have occurred in animals as well as men which have been accessible to me, let us group them together and see what deductions we can draw from them. First, as regards the animals. Those taken from ancient authors are, of course, of no service excepting as being confirmatory of what has been subsequently proved by direct experiments. In these cases it is to be noted that no particular time has been assigned as a limit beyond which spermatozoa are not found until we come to the letter which was published in the *American Medical Library and Intelligencer* for 1838, by Mr. Joseph Warrington, with regard to the boar. He apparently was able to impregnate a sow two days after he had been fully castrated. Then come the experiments of Obolonsky and Masuraca, in which some effort is made to give a time-limit within which spermatozoa are found in the seminal secretion after complete castration. In Obolonsky's cases, which only include two experiments, the longest limit is thirty-one days after castration, a far longer time than Masuraca had been able to note in his experiments. If you remember in Masuraca's experiments on dogs, the viability of the spermatozoa in the dog appeared to be extinct after the fifth day, for although at that date the spermatozoa were normal in appearance, they were but few in number and endowed with feeble movement. In the dog which was killed on the seventh day after the operation, the vesiculæ seminales were found to be devoid of spermatozoa. I should be inclined, therefore, to regard with some suspicion the experiment of Obolonsky, in which he found viable spermatozoa thirty-one days after castration, and to believe that some mistake had been made as to the number of days after castration in which the examination for spermatozoa had been made.

As regards the cats, four of which were experimented upon, up to the end of the first week (seven days) spermatozoa, perfectly normal in appearance but without motion, were found, but no examination was made between the seventh and the twenty-fifth day afterward on the last cat. In this animal no spermatozoa, were found, nor were there any bodies which looked at all like them. In the cat, therefore, as well as in the dog, we must place the limit at seven days.

The guinea-pigs, however, showed spermatozoa up to fourteen days after the operation, but in none of these cases, even when examined shortly after the operation (four days) did the spermatozoa seem to be endowed with motion. On the seventeenth day the same guinea-pig, which at the end of the fourteen days showed an abundant number of spermatozoa, exhibited seventeen days after the operation nothing upon examination but a diminished number of spermatozoa, with evident degenerative changes going on in the epithelial cells and elsewhere, and three days later no spermatozoa at all, so that it would appear as if the guinea-pig was capable of retaining normal spermatozoa for a fortnight after the removal of the testes.

If we come to man we are at once brought face to

[1] "Handbuch der Gerichtlichen Medezin," 1857.

face with this fact: that with the single exception of Princeteau's case we have no data to show how long after castration the human semen contains spermatozoa. That it does do so up to a certain time is shown by Princeteau, but what that limit is it is impossible to say, for he has neglected to give the length of time after castration at which the semen was examined. If, however, we argue by analogy from animal to man, we shall perhaps be justified in saying that if coitus take place within seven days after castration, impregnation of the woman may occur if all the conditions are favorable. But suppose the intercourse take place ten or fourteen days after castration, can the eunuch become a father? is he capable of procreation? To this question in the present state of our knowledge it is impossible to give a definite answer, but the probabilities are that it would be in the negative, although Gould and Pyle[1] state that spermatozoa have been found days and weeks after castration, and the individuals during this period were capable of impregnation. These gentlemen do not give any authorities for this extraordinary statement.

To sum up the conclusions at which I have arrived in studying this question, I should state them as follows:

1. In animals, for a varying period after complete castration, normal spermatozoa are found in the contents of the seminal vesicles.

2. This period varies in different animals, being six days for the dog, seven days for the cat, and fourteen days for the guinea-pig.

3. In man, clinical cases are recorded where fecundation of the female has occurred after coitus with the male who has been completely castrated, but in accepting the correctness of such statements we must remember the adage that accidents may happen in the best-regulated families. Still, Princeteau's case (if correct) proves that spermatozoa do exist for a certain time in the seminal vesicles of a eunuch, and arguing from analogy in what occurs in animals this is quite probable.

4. Still pursuing the analogy, in man, as in the dog and cat, a complete castrate *may* be capable of procreation provided the coitus occur within the first seven days after the castration.

THE IMMEDIATE AND REMOTE RESULTS OF SEVENTY-ONE ALEXANDER AND SEVENTY-ONE SUSPENSIO-UTERI OPERATIONS.[1]

By W. L. BURRAGE, M.D.,
of Boston.

The paper here presented is based on 71 Alexander and 71 suspensio-uteri operations performed by the writer during the six years from 1891 to 1897, inclusive, the first Alexander having been done August 7, 1891, and the first suspension August 1, 1893, so that a majority of the Alexanders were performed in the earlier years of this period and a majority of the suspensions in the later years. The facts in this paper are from my private operation-records written by myself on the day of the operation, with very few exceptions, and during the subsequent convalescence and whenever the patient again came under observation. With 3 exceptions, all of the 142 patients were examined by me personally at the time of their discharge, two or three weeks after the operation, and notes made of the existing condition. These notes form the basis of the immediate results here chronicled. For the remote results the patients were examined at least three months after their operations, for the most part by the writer, but in several instances where the patients were at a distance by their attending physicians, who kindly reported the results to me. Sixteen patients it was impossible to trace at all, and 7 were reported as being free from uterine symptoms, or wrote me to that effect. Reliable statistics were obtained from 62 Alexander and 60 suspension cases, 122 out of 142 cases. None of the patients died as a result of the operation. Three, upon whom the Alexander operation was performed, have since died, 2 of pneumonia and the other of unknown causes.

The Alexander Operation.—Sixty-four operations. Technic: Locate pubic spine by touch. Incision six centimeters long, nearly parallel with Poupart's ligament, the lower end of the incision being at the pubic spine. Dissection of the subcutaneous fat layers until the glistening fibers of the aponeurosis of the external oblique are brought into view. All the structures in the external abdominal ring are seized with tissue-forceps and drawn up. Here it may be said in passing that the author has never failed to find the ligament. A small hook is passed under all the tissues and is then replaced by the operator's finger. The nerve is separated from the ligament and drawn to one side. Traction is made on the ligament, and after it has been pulled out to its uterine enlargement the same procedure is adopted

[1] Candidate's paper presented for admission to membership in the American Gynecological Society at its Twenty-third Annual Meeting, held at Boston, May 24, 25, and 26, 1898.

with the ligament on the opposite side, the uterus is anteverted by bimanual touch, and the ligaments are anchored to the pillars of the ring by two ligatures of fine silk to each pillar. Silkworm gut, kangaroo tendon, and chromicised catgut were used in some instances, but fine silk as a general rule. If the ligament is much bruised it is cut off, otherwise it is left in the wound. The wounds are closed with interrupted sutures of silkworm gut passing through skin and fat, and catching up a few fibers of the aponeurosis of the external oblique so as to leave no dead space. Some of the wounds were closed with a continuous suture of either catgut or silkworm gut passed subcutaneously. The dressings consist of dry powder, aristol, or sterilized nosophen dusted on the wound, and dry gauze stuck to the skin with corrosive collodion to prevent contamination of the wound from the patient's finger or the subsequent shifting of the dressing.

Seven operations by the Edebohls' method. Slightly longer incision. Inguinal canal laid open by dividing the aponeurosis of the external oblique in the direction of Poupart's ligament up to the internal abdominal ring. Isolation of the round ligament in the canal by means of hooks, and separation of the nerve. Drawing out of the round ligament up to its uterine enlargement and stripping back of the peritoneal investment. After the other ligament has been shortened the position of the fundus uteri is verified by the operator's little finger passed through the internal ring. The edge of the internal oblique muscle is stitched to Poupart's ligament by a continuous suture of chromicised catgut, No. 2, the needle passing through the round ligament with each stitch and thus securely anchoring it. The aponeurosis of the external oblique is closed with the same stitch, which is tied with its other end at the upper limit of the wound in the aponeurosis. By this procedure there is only one knot in the entire operation. The ligament is cut off at the external ring. The wounds are closed and the dressings are applied in the same way as in the other method.

Although the Alexander operation was primarily intended for cases of retroversion without adhesions, its field has been amplified in my hands by performing it in conjunction with posterior colpotomy in cases of moderate adhesions. This was done in nine of my cases with good results. The colpotomy proved especially useful where the uterosacral ligaments were tight. Where the ovaries were prolapsed and free from adhesions the Alexander operation, in certain cases, has restored them to a normal position, but when adherent, or when the ovarian ligaments have been long, it has not done so in a majority of cases even with the aid of colpotomy.

A glance over the tabulated statistics of the 71 Alexander operations, shows that 34 are cases of retroversion free from adhesions, 7 of retroflexion free from adhesions, 28 of retroversion or retroflexion with some adhesions or with tight uterosacral ligaments, and 2 of procidentia. One or both ovaries were noted as being prolapsed in 16 cases. An inguinal hernia existed on one side in two cases, and a radical cure was effected in the course of the Alexander operation in each case. Curetting of the uterine cavity was done in every case. Amputation of the cervix and the ligature operation for hemorrhoids were each done once. Trachelorrhaphy and perineorrhaphy were performed together 7 times, perineorrhaphy alone 6 times, and trachelorrhaphy alone 9 times.

The immediate results of the 71 Alexander operations were good in all but 6, 92 per cent. Of these 6, 1 only was a total failure, the other 5 being classed as fair. The cause of the failure is not plain as the ligaments were of good size, were anchored with silk, and the wounds healed by first intention. One ligament broke off in the course of the operation in five cases. As a result, the uterus was in the first degree of retroversion at the time of the patient's discharge in 3, and later, completely retroverted in all except 1. This patient went through a normal labor one year and five months after the operation, and subsequently the uterus was in good position and well involuted. The first 4 cases, taken together with one case in which there was only one ligament to shorten because of a previous ovariotomy, and in which there was an ultimate failure, would argue against trusting to one ligament to hold the uterus in place. In one or two other cases the ligament broke during the operation and was recovered by opening the entire inguinal canal and fishing for the ligament through the internal ring. In the one Edebohls' operation where the cord gave way at its uterine insertion, the fault was due to using too great force in pulling on a fatty cord in a fleshy patient through an error in not appreciating that the fundus uteri was already well up.

Pregnancy has taken place in 12 cases, 19 per cent., following operation. The pregnancy and labor were both normal in 5 of these. Of the remaining 7, 1 had a tedious labor terminated by forceps, and, following that, three miscarriages. Six years after the operation the uterus was found retroverted. It was noted in this case at the time of her discharge from the hospital after the Alexander operation that from the one-sided position of the uterus one ligament had probably given way. In another there was prolonged suppuration in the wounds and the silkworm-gut ligatures which had anchored the liga-

ments came out. Here the uterus was found retroverted in early pregnancy. Another patient miscarried at seven months from overwork. The uterus was subsequently in good position. Another had pain in the left groin while pregnant, and her labor was slightly tedious. The uterus was in good position afterward. Another is now pregnant in the early months, while still another was eight-months' pregnant when last seen and had had no unusual symptoms. Another had a normal pregnancy, but the labor was long and the placenta was adherent requiring manual extraction, which was followed by sepsis. Five weeks after labor the uterus was found retroverted and adherent, a condition not to be wondered at in the light of the sequelæ of the confinement, but two months afterward it was small and in good position. To sum up: Pregnancy and labor were both normal in five cases; pregnancy was noted as being abnormal in the remaining cases three times; labor abnormal three times; pregnancy normal three times, and labor normal once. Abortion resulted from the operation in no case. The uterus was retroverted following labor in 4 cases.

The tables show that out of 62 cases examined the ultimate results were good in 48, 77 per cent., and failures in 14, 23 per cent. The other 9 cases were classed as unknown. It is to be remembered that of the 14 failures, 6 were immediate partial or complete failures also, leaving 8 cases in which the uterus became retroverted subsequent to the discharge of the patient. Four of these became retroverted, as already stated, after a subsequent labor. It is noticeable also that all of the immediate partial or complete failures were afterward traced and the results appear again in the list of ultimate failures. The large percentage of ultimate failures is to be attributed to lack of skill on the part of the operator, most of the failures being among the earlier cases, and to the fact that the operation was sometimes performed in unsuitable cases.

A left inguinal hernia followed the Alexander operation in two instances. In one the cords were slender and the rings normal in size, while in the other the cords were very large and the rings large. The ligaments were anchored with catgut in both cases. In both the uterus was in good position ultimately. Pain in the scars followed the earlier operations where the nerves were not carefully separated from the cords, but not in the later operations. No bladder symptoms as resulting from the operation have been noted in any of the cases.

The Suspensio-uteri Operation.—Technic: For convenience of description the 71 cases may be divided into (1) those in which the uterus was suspended by attaching the fundus uteri to the parietal peritoneum, and (2) those in which suspension was accomplished by sewing the round or ovarian ligaments to the parietal peritoneum.

1. Of this class there were 58 cases, divided into 11 for the posterior face of the fundus, 11 for the top of the fundus, and 36 for the anterior face of the fundus. Permanent ligatures of silk or silkworm gut passing through muscle and fascia as well as peritoneum and constituting ventral fixation, were employed only seven times. Both ovaries and tubes were removed in two of these and one or both ovaries resected in the others. It is interesting to note here that only one of these patients has since become pregnant, and she was reported by her physician as having had pain during early pregnancy, but later to be entirely free from it. This was a case of extensive suppuration following pelvic abscess, where the adhesions between the fundus and the parietes must have been very dense.

The usual method of operating is as follows: Unless there is much work to do in the pelvis in the way of operating on the ovaries and tubes, the incision is short, six centimeters, in the median line, with its lower end not nearer than three centimeters to the symphysis pubis. The uterus is brought up to the abdominal wound by two fingers of the operator's left hand. A slender, full-curved needle with a round point, and threaded with a carrying thread, is passed through the transversalis fascia and peritoneum at a distance of one centimeter from the right edge of the incision, then through a deep bite of the fundus uteri, and finally through the peritoneum and transversalis fascia on the left edge of the incision. The carrying thread is used to draw through a strand of No. 2 or No. 3 chromicised catgut. Two or three stitches are inserted, that through the top of the fundus being quite superficial in the uterine tissue. Care is observed in not interfering with the uterine ends of the tubes and in not attaching the fundus too close to the pubes. Tying the uterine sutures closes the peritoneum except for a short space in the upper part of the wound, which is closed with a continuous stitch of fine catgut. The linea alba is dissected out and the bellies of the recti are approximated by two or three interrupted stitches of No. 2 chromicised catgut, each stitch catching up the underlying peritoneum so as to leave no dead space. The fascia is closed by a continuous suture of the same material and the skin by a subcutaneous right-angled silkworm-gut suture. Dressings of dry powder on the line of the wound and dry sterile gauze stuck to the surrounding skin by corrosive collodion.

2. By the round or ovarian ligaments, 13 cases, 8 of the former and 5 of the latter. The incision into the peritoneal cavity is the same as in suspension of

the fundus. If by the round ligaments, the ligament on one side is pierced at a point three centimeters from the uterus by a round-pointed, full-curved needle carrying fine silk. The needle is then made to pierce the peritoneum and overlying transversalis fascia at a point two centimeters outside of the line of the abdominal incision and five centimeters from the symphysis pubis. Another stitch is placed on this side and two similar stitches on the opposite ligament and all are tied. In cases where the ovarian ligaments are very long, allowing complete prolapse of the ovaries, the same procedure is carried out with the ovarian ligaments as with the round ligaments, two fine silk stitches to each ligament being used. The abdominal wound is closed and dressed as in the other form of suspension.

Glancing over the tables it appears that in 40 cases suspension was done for retroversion, retroflexion, or retroposition accompanied by more or less extensive adhesions; in 19 cases for retroversion, retroflexion, or retroposition without adhesions; in 6 cases for prolapse; and in 6 cases to prevent ovarian prolapse, or, after the removal of severe grades of inflammatory affections of the ovaries and tubes, to prevent retroversion of the uterus into the raw surface left by their removal. Both tubes and ovaries were removed in 13 cases, one ovary in 34 cases, the ovaries and tubes were resected in 17 cases, and nothing was done to the ovaries or tubes in 15 cases. Every effort was made to preserve some healthy ovarian tissue and, considering the severity of many of the cases, the number in which both ovaries and tubes were removed is a small one.

The immediate results were good in every one of the 71 patients except that 5 had mural abscesses. As far as the uterus was concerned it was suspended in good position at the time of the patient's discharge. As regards symptoms, the pain immediately following was inconsiderable in almost all. A few patients complained of a drawing feeling in the uterine region on coughing and sneezing during the first days after being up and about. In no case was there interference with micturition.

Subsequent pregnancy has resulted in 7 cases, or 12 per cent. Of these, 5 women have had normal pregnancies and normal labors, and one of them is now five-months' pregnant for the second time, and is not having pain. The remaining 2 of the 7 are now pregnant. One, four months along, is having no special symptoms to mark this pregnancy from her former ones; the other, six months along, has already been referred to as having had pains but as now free from them.

In the 5 cases in which normal pregnancy and labor has taken place the uterus was found in good position two months after labor in one, a case of suspension by the anterior face of the fundus, and in another, a case of suspension by the round ligaments, the uterus was found retroverted two years later. One of the remaining three is now pregnant again, and of the other two it has been impossible to obtain the facts because the patients live at a distance.

When we take into account the fact that a majority of the suspension operations have been done during the past year and a half, it is not surprising that fewer of these women have become pregnant than has been the case with those upon whom the Alexander operation was performed, to say nothing of the suspension operation having been accompanied by the removal of one or both ovaries in 66 per cent. of the cases as against the Alexander, in which, with one exception, the ovaries and tubes were not operated upon.

Of the 60 patients examined as to ultimate results, the results were good in 56 and bad in 4. Four of the 12 patients counted as unknown, wrote that they were relieved of their symptoms. Not including these we have 93 per cent. of good results and 7 per cent. of failures. Only one of the failures followed pregnancy, and that one was a case of suspension by means of the round ligaments. In another, also a suspension by means of the round ligaments, the ligaments gave way ultimately. The other two suspensions were by the anterior and top of the fundus. In one there was suppuration in the wound, while in the other, the union was by first intention, but there was a question as to the patient having had an abortion not long after the operation. There was a small hernia in the cicatrix in one case two years after the operation. There had been suppuration in this wound while the patient was in the hospital. In no case were there symptoms pointing to strangulation of a loop or loops of intestine due to the suspending ligaments or bands.

In contrasting the Alexander with the suspension operation as to immediate and remote results one is impressed at the outset with the fallacy of statistics. Knowing as we do that many of the Alexander operations have been performed on patients upon whom, in the light of a larger experience, we should elect to do the suspension operation, and also that the Alexander operations on my list having been begun so much before the suspensions that there has been with the former a longer period of time in which to allow of pregnancy to occur and of late results to be gathered, we are prepared to have the Alexander operations make a poorer showing. The immediate results of the Alexander operations were 92 per cent. good, as against 100 per cent. good for the suspen-

sions. The remote results of the Alexander operations were 77 per cent. good, as against 93 per cent. good for the suspensions. Hernia followed the Alexander operation in 3 per cent., and the suspensio uteri in 1.7 per cent. Twenty-five per cent. of the subjects upon whom the Alexander operation was done who became pregnant had tedious labors. No tedious labors after the suspensio-uteri operation have been noted. One of each class of patients had excessive pains during the early months of a subsequent pregnancy. One-third of the Alexander subjects had the uterus retroverted after labor. In the suspension cases the statistics as to this fact are defective. Only one patient was known to have had retroversion following labor.

Pains in the scars have been noted after certain of the earlier Alexander operations, and rarely these pains have persisted a considerable length of time. These may be contrasted with the drawing sensation noted after some of the suspension operations, but the drawing sensation has never been of more than temporary duration. After neither operation was there interference with micturition, and neither operation was the cause of abortion or miscarriage.

General conclusions: (1) The Alexander operation is preferable to the suspensio-uteri operation because it seeks to support the uterus by its natural ligaments. (2) The Alexander operation is indicated in retroversion, retroflexion, and retroposition without ovarian disease. (3) In retroposition with tight uterosacral ligaments posterior colpotomy for the purpose of dividing the tight ligaments may be performed with advantage, together with the Alexander operation. (4) In ovarian prolapse, especially if the ovarian ligaments are long, the Alexander operation cannot be depended on to raise the ovaries into a normal position. (5) One round ligament is not sufficent to maintain the uterus in place. (6) The Edebohls' operation, although requiring a longer time for its performance than the operation at the external ring, is the preferable operation because by it the round ligament, being uncovered in the entire length of the inguinal canal is less liable to be broken; also, because this method does away with the need of anteverting the uterus bimanually in the course of the operation; and finally, because of the secure manner in which the ligament is anchored and the inguinal canal closed, making subsequent hernia impossible. (7) Although the Alexander operation leaves two scars on the abdomen, they are so situated as to be covered by the pubic hair and are subsequently less of a disfigurement than is one scar in the median line. (8) The suspensio-uteri operation is indicated in retroversion, retroflexion, and retroposition with ovarian or tubal disease, whether inflammatory affections or prolapse. (9) The best method of performing the suspension is by means of absorbable ligatures passed through the anterior and upper portions of the fundus uteri and through the parietal peritoneum and transversalis fascia only. Thus an elastic band is created between the parietes and the uterus which maintains the uterus in place and does not cause interference with the enlargement of the anterior fundus during subsequent pregnancy. (10) Suspensio uteri leaves but one weak spot in the abdominal parietes predisposing to hernia, instead of two, as in the Alexander operation. (11) In the great majority of cases, neither operation is the cause of complications in subsequent pregnancy. Whatever complications do occur are not of a serious nature. (12) In all cases of doubtful diagnosis in which the condition of the ovaries and tubes cannot be determined accurately the suspensio-uteri operation is to be preferred to the Alexander operation.

YELLOW FEVER AND THE ABUSES OF QUARANTINE IN THE SOUTH DURING THE EPIDEMIC OF 1897.

By DILLON J. SPOTSWOOD, M.D.,
of Mobile, Ala.

Thus great Achilles who had shown his zeal
In healing wounds, died of a wounded heel.
—O. W. Holmes.

On the 13th day of September, 1897, the first case of yellow fever in Mobile was officially reported to the local board of health by Dr. Edwin L. Marechal. Though an epidemic of suspicious fever had been prevailing in Ocean Springs, Miss. (distant about 50 miles from Mobile and 80 from New Orleans), since July, 1897, and which had on two occasions been investigated by "experts" from Louisiana, Alabama, and Mississippi, not until September was it recognized as yellow fever. During all of this time constant communication had been kept up between Ocean Springs, Montgomery, Mobile, New Orleans, and other towns of importance in the Gulf region.

On the 14th day of August, 1897, Dr. J. M. Holloway of Louisville, Ky., reported to the Louisiana and Mississippi boards of health that he had treated a *well-marked* case of yellow fever in the person of a man recently arrived from New Orleans. Yet the prevalence of yellow fever in New Orleans was not officially known until September, 1897. Though there had been a great deal of fever prevailing in Mobile and some cases of a suspicious nature as early as July 26th, not until September was a single case reported as at all doubtful.

Is it not pertinent, under the circumstances, to ask which of the many State and local boards of

health was responsible for the almost criminal negligence of allowing an infectious disease to be spread broadcast through the country? The reign of terror under the régime of the "shotgun quarantine" and the numerous town, city, and county boards of health has been already too vividly described by the press despatches and correspondents of our daily papers to require more than brief mention. There were two occurrences, however, that were so lawless, unnecessary, and brutal in their nature that one shudders to think that selfish fear could make such unfeeling, canting cowards out of human beings. The writer details them as of special interest. On Septemper 5, 1897, eight days before a case of yellow fever was reported in this city, Mrs. D., an old lady, left here to visit her son in Selma. Her stay there was uneventful until September 14th, when she was informed by the authorities that she must leave the town and go to the "detention camp" some miles distant and remain for twenty days before returning to the city. She protested that she had violated no quarantine law as she had left Mobile eight days before yellow fever had been reported. In spite of her protests and her son's influence she was dragged from her comfortable home, placed in a leaky country log-cabin, not good enough for pigs to occupy, and fed upon food of which a decent cornfield negro would have complained. To cap the climax, the food was served on tin plates without knives or forks. She begged them to allow her to return to Mobile and face the danger of infection, or to go anywhere rather than die of hunger and neglect. But all to no avail. She was compelled to remain for twenty days, contracting rheumatism, from which she has not yet recovered. And all of this was done by order of the "*august*" Dallas County Board of Health, composed of medical men (?). Shortly after yellow fever had been reported a train-load of refugees was passing through Montgomery, en route to Atlanta. Before reaching Montgomery, every window and door had been shut by order of the "health" authorities. A gentleman who had been almost overcome with the heat and dust had the courage to open a window—immediately a gun was pointed at his head and he was informed unless that window was closed at once he would receive the contents of the gun.

Are there recorded in Spanish history any acts more brutal than those perpetrated by "shotgun quarantines"? A condition of affairs little better than anarchy existed for more than two months in the Gulf States. Federal, State, county, and municipal health authorities were in constant conflict.

To show the utter disregard in which the State board of health and State health-officer were held by county boards: The health-officer of Alabama issued an address to all the county boards of the State, instructing them to recognize health-certificates of the U. S. Marine Hospital Service after the holders had been subjected to ten-days' detention in the Government camp. Without an exception they refused to follow the instructions of the health-officer, the majority making twenty days the limit of detention. Not only did the county boards treat with contempt the State health-officer's instructions, but they actually restricted his movements. He attempted upon one occasion to go from Montgomery to Mobile and was informed by the Montgomery board that if he visited Mobile he would be quarantined and not allowed to return for twenty days. Nor was the condition of affairs in towns and cities any better. A "rigid" house quarantine was established by the Mobile Board of Health, which consisted of one guard stationed at the *front gate* of the infected house, the back gate and side entrances being unguarded and free to exit and entrance. Much to the disgust of the olfactories, and little to the discomfort of microbes, crude carbolic acid was freely sprinkled in the streets, while backyards and alleys were neglected. But the most absurd performance was the senseless quarantine that was kept up during the entire epidemic against other infected cities, while every portion of this city was infected.

The maintenance of the house and other quarantine cost thousands of dollars that might have been spent in improving the wretched sanitary condition of the city.

Some quarantine regulations were really amusing: A barrel of carbolic acid that was shipped to Selma had to be thoroughly fumigated before it was allowed to be landed in that town. A large load of rocks from a hundred miles up the Tombigbee River that passed down the river (by the city) had to be "disinfected" before it was unloaded at Fort Morgan, where the material was to be used in building harbor defenses. No doubt the health authorities had detected numerous "yellow microbes" upon the wharves, anxiously awaiting the approach of the barge, to pound upon the unsuspecting rocks. So absurd were the quarantine regulations imposed by the Selma health authorities and the intervening counties that the officers of the Mobile and Birmingham Railroad had to discontinue all trains over their road until quarantine was raised. Is it any wonder then that the quarantine has a much greater terror for all sensible people than the dreaded yellow fever itself? Is it any wonder that all classes of business men cry aloud to the government to save them from the local quarantine fiend and establish a national

quarantine, based upon reason, justice, and humanity; quarantine regulations that may be enforced without paralyzing business and stifling commerce? Would it not be a wise step for the people of the South since the war with Spain has ended to discuss some plan to repel an invader more fatal to human life and the prosperity of the country than a hostile host of armed men? Should not a foreign disease be treated as a foreign enemy and the entire strength of the nation be centered in the federal government to deal a death-blow to pestilence; to establish system and order, where chaos and confusion now reign supreme, among local quarantines? In the name of humanity, of decency, of common sense and reason, let the medical profession implore the people of the South to change their present system of criminal quarantine regulations that has been such a reproach to our honored profession.

Having in the first part of this article given a general idea of the outrages perpetrated upon the people of the South in the name of quarantine, the last part will be occupied in giving the symptoms and treatment of a few cases of the disease.

It is interesting to know that the death-rate in yellow fever in private practice is less than ten per cent.; yet upon the advent of yellow fever in the early fall out people rush at a breakneck speed to localities where scarlet fever, smallpox, diphtheria and typhoid are indigenous, any one of which has a higher death rate than yellow fever. When seen in time and properly treated yellow fever is to be far less dreaded than typhoid with all of its complications and dreaded accidents that may occur at any hour.

The greatest difficulty in the management of yellow fever is the diagnosis. As the veteran Creole physician, Faget, of New Orleans has tersely remarked: "Is the diagnosis of yellow fever well established? It is not."

From severe attacks of remittent and dengue it is exceedingly difficult to differentiate. It is entirely out of the question to be at all dogmatic in the diagnosis of yellow fever. The following prominent symptoms which are by no means pathognomonic may be noted in well-marked cases: Want of correlation in pulse and temperature; slow pulse and high temperature. Besotted or bloated appearance of the face and eyes as if the patient were just recovering from a debauch. A full and uneasy sensation about the stomach, with tenderness upon palpation. Intense pain in head, back and limbs. Neuralgia of eyelids that may persist throughout the attack. About the third or fourth day albumin may appear in the urine, but it is absent in a great many cases. There may occur suppression of urine, also, about the fourth or fifth day, which may be considered among the most dangerous symptoms. Jaundice sometimes appears as early as the third day, but is oftener postponed until the later stages. It may be general or circumscribed, the icteroid hue being confined to the conjunctivæ, forehead, and cervical region. Late in the attack the pulse may become very rapid and weak, the patient sinking rapidly. Hemorrhages sometimes occur from the nose, lips, gums, and bowels. Fissured lips, with a serosaguinous discharge and the formation of dark-looking scabs, are common in severe cases.

The febrile paroxysm is by no means limited to seventy-two hours, as is dogmatically insisted upon by some authorities. The fever in many cases lasts for six, seven, and sometimes ten days in the severer cases. During the stage of calm, which is marked by a defervescence in temperature and a decline of the more acute symptoms, the patient often expresses himself as feeling much better. This is the most critical part of the disease, the time of occurrence of the dreaded black vomit and suppression of urine. The inexperienced physician might be inclined to believe that the crisis had passed, but really this period of the disease is attended by more danger than any other.

Is it possible to make a diagnosis of yellow fever under three or four days? It is not. At least three of the prominent symptoms should be present, together with a history of exposure to infection. From fatty infiltration of the heart the general circulation is impaired, hence if a vascular portion of the body, as the face, forehead, or neck be pressed upon with the finger, a white spot is made, and upon the removal of the finger the circulation is much longer in returning to the anemic area than in other cases. The sluggish circulation accounts for the dusky, livid color of the face and injected conjunctivæ.

I have now described briefly the most prominent symptoms of yellow fever, yet any physician who has had anything like an extended experience in the treatment of fevers will tell you he has seen the identical symptoms in both remittent and dengue. Fortunately for science and the reputation of the physician, death almost invariably occurs among the first two or three cases in the beginning of an epidemic, and an autopsy removes all doubt. It must be very evident to the practitioner, even of limited experience, that in a self-limiting disease, whose etiology is a specific poison not yet definitely known, the only treatment to be thought of is to combat the symptoms as they appear. No routine is possible in contending with this fever. However, there are certain rules that must be adhered to; these more properly come under the direction of the nurse: (1) Keep your patient in the recumbent position during the

entire attack. Never allow him to get up to void urine or move the bowels. Always use the bedpan for this purpose. (2) Have the room thoroughly ventilated, but avoid drafts on the patient. (3) Keep him quiet, allowing no one in the room except the attendants and near relatives. (4) Use only the covering that is comfortable for the patient. No good and much harm is derived from profuse sweating under blankets. (5) Never crowd the stomach with fluids. Use crushed ice and cold drinks in small quantities often repeated. (6) If possible, keep the patient in ignorance as to the nature of his disease. People have been known to die of fright when told they had yellow fever.

According to Sternberg the secretions in the alimentary canal become very acid during an attack of yellow fever. To neutralize this condition he has recommended the following:

℞ Hydrarg. bichlorid. . . . gr. ⅓
Sodii bicarb. . . . . ʒ iv
Aquæ . . . . . Oij.
M. Sig. Two tablespoonfuls, ice-cold, every two hours.

I have substituted the following with excellent results:

℞ Sodii bicarb. . . . . ʒ iv
Aqua menth. pip. . . . . Oij.
M. Sig. Two tablespoonfuls every two or three hours, ice-cold or with crushed ice.
℞ Sodii sulphocarbolatis . . . ʒ ij.
Ft. pulv. No. 8. Sig. One powder every three hours with soda solution.

The sulphocarbolate of sodium very often quiets the stomach where the bichlorid causes nausea and vomiting, besides the antiseptic effect is equally as efficient as the mercuric salt. For hyperpyrexia there is no better antipyretic than ammonol, gr. vj to gr. viij, with a tablespoonful of whisky or a teaspoonful of aromatic spirits of ammonia every two hours until the fever falls below 102.5° F. I have not in a single case noticed any depression, cold sweating, or cyanosis from the use of this remedy, as often occurs with the use of the other coal-tar products.

At the outset of an attack, if a purgative is required (which occurs ninety-nine times out of a hundred), the following should be prescribed:

℞ Hydrarg. chlor. mitis . . . gr. vj
Sodii bicarb. . . . . gr. vj
Aq. menth. pip. . . . . *m.* ss
Sacchar. lac. . . . . gr. x.
Ft. pulv. No. 2. Sig. One powder at once, repeat and in six hours if bowels have not moved.

A tablespoonful of good brandy or whisky in a wineglassful of crushed ice should be given every three or four hours. As the stomach for the first five or six days of the attack is not capable of digesting any kind of food none should be given; the alcohol must be depended upon to supply the required nourishment. If conditions make it necessary, liquid food by the rectum may be resorted to. It is of the utmost importance that nothing be given that in the least deranges the stomach, for there can be no doubt that black vomit is due to the constant irritation of the stomach by foods and medicine. It were better that *all* medicine be discontinued than for the patient to have an irritable stomach and have him exposed to the danger of black vomit. Where there is great depression and an unusually slow pulse, strychnin sulphate, $\frac{1}{40}$ of a grain, and nitroglycerin, $\frac{1}{100}$ of a grain, should be given every three hours, and the dose of alcohol increased. In one of my cases the pulse ran as low as 39 to the minute, when strychnin and nitroglycerin were given every two hours for two days with good results.

For suppression of urine good results have been obtained from calomel in ½-grain doses every hour or two. Hot applications and counterirritation over the kidneys have given favorable results. The fatty infiltration of the heart and other important organs requires that the convalescence of this fever be handled very cautiously. The diet should be most guarded and the return to normal feeding must be accomplished in the most careful and gradual manner. Many a life has been sacrificed to a whim of the palate. Out of some two hundred cases of fever treated by me last fall thirty were yellow fever, and it is not without a feeling of pride that I can truthfully state that I lost not a single patient. The clinical histories of three typical cases are herewith appended.

Case I.—W. C., male, aged twenty-four years; American, native of Mobile, Ala. Temperature ranged from 104° F. on the first day of the disease to 98½° F. on the tenth day; pulse ranged from 114 to 50 during the same period. For five days after the tenth day the pulse ranged from 40 to 50 with normal temperature and great prostration. Albumin appeared in the urine on the third day. Terminated in recovery.

Case II.—G. K. C., male, aged thirty-five years; American, native of Monroe County, Ala. Temperature first to tenth day ranged from 104° F. to normal; pulse from 84 to 58. On the tenth, eleventh, twelfth, and thirteenth days the pulse went as low as 39 and was almost imperceptible at the wrist. Recovery.

Case III.—Jno. R., male, aged twenty years; American, native of Mobile, Ala. Temperature ranged first to tenth day 102°F. to normal; pulse, 88 to 80. There was intense neuralgia of the eyelids and hemorrhages from the gums, lips, nose, and bowels. Recovery.

In the long list of details, which, of course, are too numerous for all to come within the scope of this

article, the writer has forgotten to mention the management of nausea and vomiting. A great many remedies that have been used in ordinary cases of sick stomach may be resorted to. I have found cocain hydrochlorate in ¼-grain tablets dropped on the tongue and swallowed rapidly will relieve the most intense nausea. Given in solution it is absorbed by the mucous membranes before reaching the stomach. A small ice-bag or an ice-cold towel placed low down on the throat and the face sponged with cologne-water will greatly assist the cocain. Three grains of bismuth subnitrate and $\frac{1}{10}$ of a grain of calomel given with 5 grains of sugar of milk and $\frac{1}{10}$ of a drop of oil of peppermint every hour or two will sometimes relieve the patient. The old remedy of burning the epigastrium thoroughly with a mustard plaster should never be neglected. Finally, when all have failed, morphin and atropin, hypodermically, may be cautiously used. The phosphate of codein should be tried first.

THE EFFICIENCY OF GLYCERINATED VACCINE VIRUS AS USED BY THE VACCINATING CORPS OF THE NEW YORK HEALTH DEPARTMENT IN PRIMARY VACCINATIONS.[1]

By F. S. FIELDER, M.D.,
OF NEW YORK:
MEDICAL INSPECTOR, NEW YORK HEALTH DEPARTMENT.

THE following report is presented upon the efficiency of the glycerinated vaccine virus produced by the Vaccine Laboratory, and used by the Vaccinating Corps of the Division of Contagious Diseases of the New York Health Department during the thirteen months ending December 1, 1897. The report is based on the number of *primary* vaccinations performed and inspected, as shown by primary lists furnished by the vaccinators. All cases have been disregarded in which for any reason the results of the vaccinations were not learned. The number of vaccinations performed and inspected during November and December, 1896, was 1062. During 1897 almost all of the work was done during the months of April, May, June, September, October, and November, and the number of vaccinations inspected was 19,742, making a total for the eight months of 20,804. Of these, 20,420 were successful and 384 failed, the percentage of successes being 98.106. Some of the vaccinators failed to indicate upon their lists the laboratory numbers of the different lots of virus which they used, so that it has been impossible to classify all the vaccinations according to the virus employed, but a special effort has been made to trace the failures back to the virus used, and this has been successful in most instances. The accompanying list shows the source of the virus in the unsuccessful cases:

Animal No.	No of Failures.	Remarks.
173	1	
177	2	
195	9	
197	1	
199	171	
202	8	1 patient 10 years old. 1 " 8 " "
203	17	1 " 13 " " 1 " 35 " " 1 " 41 " "
206	25	1 " 47 " " 1 " 36 " " 1 " 23 " " 1 " 12 " "
209	8	1 " 19 " "
215	1	
216	70	1 " 24 " " 1 " 30 " "
217	1	
218	3	
220	11	1 " 12 " "
221	14	
222	2	
228	3	
232	1	
236	2	
239	5	
241	4	
243	1	
245	3	
246	3	1 " 13 " " 1 " 8 " "
247	2	
282	1	
286	1	
288	4	
289	1	
296	1	
Unknown	8	1 " 10 " " 1 " 24 " "
Total.	384	

From this list it appears that the virus from two particular animals, calves 199 and 216, was responsible for a very large proportion of the failures. From calf number 199 the number of vaccinations inspected was 428, of which 257 were successful and 171 failed, the percentage of successes being 60. From calf number 216 the number inspected was 242, of which 172 were successful and 70 failed, the percentage of successes being 71. Of the 384 failures, then, calf number 199 and calf number 216 are responsible for 241, or 63 per cent., leaving 141 failures, or 37 per cent., distributed among 28 other lots. Excluding the cases vaccinated with the two lots of particularly poor virus, we find in 20,134 cases, 19,991 successes and 143 failures, the percentage of successes being 99.29.

An examination of all the reported failures with reference to the ages of the persons vaccinated, shows that 15 cases, though classed as "primaries," were so old that it is more than likely that they were revaccinations. Excluding these, we have 20,119

[1] From the Vaccine Laboratory of the New York Health Department.

cases, 19,991 successful, and 128 failures, the percentage of successes being 99,363.

The virus issued by the vaccine laboratory usually retains its activity for at least six months, and it is not easy to explain why lot 199 deteriorated so quickly. The following facts may be stated:—Calf, number 199. (1) The vaccination "took" well on the animal. (2) The pulp collected was ground up with chemically pure glycerin in the proportion of 4 c.c. of glycerin to 1 gram of pulp. (3) The virus on original clinical test, and in first retest "took" well, but it showed signs of deterioration only two months after collection (a few days after the virus was issued to the vaccinators). It might at first be supposed that too much glycerin was added, for most of the virus issued has been made up in the proportion of 2 or 3 c.c. of glycerin to 1 gram of pulp, but we are obliged to abandon this view when we find that all the lots from 191 to 202 were diluted 4 to 1, and that while calf 199 was responsible for 171 failures, only 18 failures are charged against the eleven other lots.

In connection with calf number 216, the following facts may be stated, but it must be admitted that they hardly furnish a satisfactory explanation of the failures charged against the virus: (1) The vaccination "took" fairly well, though not ideally, upon the animal. At the time of collection the vesicles were somewhat flattened instead of being well elevated. (2) The virus was made up with 3 c.c. of chemically pure glycerin to 1 gram of pulp. (3) On the original test the virus gave evidence that its quality was somewhat below the very high standard reached by most of our virus. This test consisted in 5 primary cases, each vaccinated in 3 spots. The result, instead of being 15 "good" vesicles, was 15 vesicles of which two were "good," 11 were "fair," and 2 were "small." Two weeks later a retest of 1 case, vaccinated in 3 spots, gave 3 vesicles, 2 fairly good, and 1 fair, though rather small. Further retests were as follows: at 1 month after collection 1 case gave 3 "good" vesicles; at 2 months, 1 case gave 3 "good" quality, fair-sized vesicles; at 3 months, 1 case gave 3 "good" vesicles; at 4½ months, 1 case gave 3 good quality but small vesicles; at 5 months, 1 case failed in all of the 3 spots of insertion; at 6½ months, 1 case gave 3 good vesicles again.

It will thus be seen that although the virus from calf 216 was not originally as ideally good as most of the virus issued by the vaccine laboratory, yet, in the hands of the clinical tester, it continued for more than 4 months to "take" in every spot in which it was inserted. This, of course, carried it beyond the date of its issue to the vaccinators.

SUMMARY OF RESULTS—PRIMARY VACCINATIONS.

Nov. 1, 1896 to Dec. 1, 1897.	Successful.	Failed.	Total.	Percent. Success.

Fifteen probable revaccinations excluded.....	19,991	128	20,119	99.363

ADDRESS.

THE CORNELL UNIVERSITY MEDICAL COLLEGE.[1]

BY J. G. SCHURMAN, A.M., D.Sc., LL.D.,
PRESIDENT OF CORNELL UNIVERSITY.

THE origin of the Cornell University Medical College reminds one of the birth of Minerva. That goddess, you remember, sprang full-armed from the brain of Jove. Our medical college is almost as miraculous a creation. A year ago no one dreamt of its existence. To-day it stands before the world with an actual organization and a potency of achievement which presage its manifest destiny as the America acropolis of Æsculapius.

I know no better illustration of Professor Huxley's saying that "the question of medical education is, in a very large and broad sense, a question of finance." Most assuredly this institution could not have come into existence but for the unlimited capital which a wise head and generous hand have furnished for its foundation and support. That munificent gift is the offering to humanity of one who feels deep sympathy with his suffering fellowmen and who believes that their lot is to be ameliorated by the elevation of medical education. "I suppose," this generous benefactor once said to me, "we all want to do some good in the world, and I should like to do something by improving the education of that profession which cares for the lives of men, heals their wounds, and alleviates their sufferings." Of such a compassionate heart and intelligent understanding was the Cornell University Medical College born. By the star of our nativity, therefore, we are dedicated to noble things. With such a consecration, which will prove a never-failing inspiration, let us, in that spirit of fraternal union which gives irresistible strength, strive by zeal, diligence, and wisdom for the fulfilment of the high trust committed to us. Here and now let us resolve that, so far as in us lies, the humane and lofty purpose of our founder shall be accomplished.

I have no doubt whatever that we shall succeed in our task. If our hopes are sanguine, if our am-

[1] Delivered at the opening exercises of Cornell University Medical College at New York, October 4, 1898.

bitions are high, if we presume to make our aim a goal yet unattained, do we not also set out on our career under circumstances more favorable than have ever smiled upon any similar institution since medical education began with the University of Salerno? Much may be expected of this medical college for much has been given to it. I speak not only of capital, which, however, is forthcoming for every reasonable object. Nor have I in mind material structures, though our local habitation in spacious proportions will soon rise, like a thing of splendor and beauty, to crown this section of our great metropolis. My thought is rather of *men*. For it is true now as always that, though money be the indispensable condition, the real and essential cause of the success of any institution is to be found in the *men* who are its active soul. If, therefore, my expectations are pitched high for this medical college, it is primarily because it is organized with a remarkably strong, though still incomplete, staff of instruction—a body of picked men, a corps of physicians and surgeons whose practice puts them in the van of their profession, and whose gifts as teachers, already exhibited in other schools, have won for them the united admiration of rival bodies of students. Personally I count it a peculiar privilege that I am to have the honor of association with these distinguished gentlemen in the elevation of medical education and the advancement of medical science in this great city of New York. I regret that I am not better qualified to aid them. I am not a physician or the son of a physician. And yet, to be quite frank with you, I wish I had some qualification that might commend me to the confidence of this portion of the medical public. But I have neither rags nor tatters to hide my utter nudity. Perhaps, however, your sympathetic imaginations will invest me with at least the semblance of a decent robe if I tell you that my *Alma Mater* has on her rolls, not only the name of Huxley, but those eminent medical practitioners and reformers, Sir Henry Thompson, Sir William Jenner, Henry Maudsley, Sir Morrell MacKenzie, and, greatest name of all and of the century, Sir Joseph Lister. And you may be kind enough to think that a college which turns out such men is not likely to breed in any of its sons indifference to, or lack of sympathy with, the science and art of medicine.

The work and fame of this medical college, then, are in the hands of its faculty. You will agree with me that they are in safe keeping there. But I should not have done justice to my own feelings, or fully described the support of this institution, if I did not mention another feature of its existence, a feature which I may be pardoned for thinking of cardinal importance, as it explains and justifies—especially as nothing I have to say would else justify—the prominence which has been given to my unworthy self in these proceedings. This medical College is a department of Cornell University. And by that description I mean to say that it is a real, integral, and vital part of the university. In other words, the legal corporation, known as Cornell University, has exactly the same rights, powers, responsibilities, and jurisdiction in regard to this new department as it has hitherto exercised in regard to every other department of the university. The only difference is that a wealthy philanthropist gives us an endowment for the conduct of the department of medicine while many of our other departments are unendowed and must take their chances of support out of the general funds of the university. This difference is momentous indeed from the point of view of permanent and assured vitality and efficiency. But considering the mere fact of organization I repeat that the Medical College stands on precisely the same footing as the Academic Department, the College of Law, or the Sibley College of Mechanical Engineering. The faculty in every case is charged with the educational administration of its respective college, but all business is conducted and all appointments are made by the Board of Trustees of Cornell University. The members of the Faculty of Medicine receive fixed stipends like the professors in other departments; and as they have nothing to do with the business affairs of the college, so they have no interest in the fees received for tuition, which are turned into the treasury of Cornell University. The faculty, in a word, is an educational body.

You may ask if it is possible for the Board of Trustees of Cornell University, meeting in Ithaca, to manage wisely the affairs of their medical college in New York? Let me remind you, by way of answer, that this is an age of telegraphs, telephones, and rapid travel. But not only this. Following a precedent already established in connection with some of the other colleges of the university, the Board of Trustees have established for the Medical College an advisory council, consisting of the dean and two members of the Faculty of Medicine, three trustees (who are residents of New York), and the president of the university as chairman, whose duty it is to digest all business affecting the medical college and make recommendations thereupon to the board for formal action. This system, which insures a thorough consideration of every question from every point of view, promises the happiest results. The council meets once a month, on the day following the monthly meetings of the faculty.

So much of the anatomy and physiology of the Medical College as one of the organs of Cornell Uni-

versity. Let me now turn to the inner and ideal side of this relationship.

Though the physical distance between the Medical College and the other departments of Cornell University is greater than it is in the case of Harvard or Columbia, I believe I am not mistaken in the belief that the connection is really closer. For the men of the first and second years are free to study either here or in the Academic Department at Ithaca, while in the case of the women they are even required to go to Ithaca. It is a characteristic of Cornell University, whose charter consecrates it to both "liberal and practical education," not to draw sharp lines of demarcation between the academic department and the professional schools. It has always been recognized that when the curriculum of the classical colleges was enlarged so as to provide for the sciences of Nature and the modern humanities—as from the beginning it was enlarged at Cornell—then the Academic Department, instead of withdrawing to the seclusion of an imaginary superiority, in fact became the foundation and the fruitful ally of every technical, scientific, or learned profession. Nearly half the work of our engineering courses is given in the Academic Department. And we were glad to make a similar arrangement for the medical student. While on this subject of inter-relationship I may add that the graduates of every one of our professional colleges enjoy equally with the Bachelors of Arts the privilege of voting for alumni trustees. I suppose we may soon expect to see an influx of medical members into our board!

There is another feature of Cornell University which is of no little importance in the consideration of medical studies. From the beginning we have given prominence to the natural sciences. Of course the physico-chemical sciences were indispensable to the success of our engineering departments. But though we had no medical school, which imperatively called for the biological sciences, these were nourished with equal care and assiduity. I need only mention the name of Professor Wilder as a guarantee of the quality of the work done. But not only were physiology, anatomy, and the kindred sciences cultivated by the university; their indispensable importance to the physician and surgeon was recognized at a time when students at medical schools were accustomed to hear "lectures upon surgery without any knowledge of anatomy and upon therapeutics while ignorant of physiology" (Dr. Wilder in *Boston Medical and Surgical Journal*, June 24, 1875). Indeed, within two years after its opening in 1868, Cornell University had arranged a four-years' course in natural history leading to the degree of Bachelor of Science, which was well adapted to the needs of students who contemplated the study of medicine; and in 1878 for such students as could not take this full course, a shorter two-years' course was provided, in which a large amount of time was devoted to practical work in anatomy, physiology, histology, and chemistry. Any one who knows how these sciences were in those days neglected in the medical schools will perhaps feel that there is a certain propriety or poetic justice in the endowment which Cornell has at last received for the establishment of a great medical department.

This is the attitude of Cornell University to the sciences of Nature; this is what she has done for the scientific preparation of students for work in the medical schools. Is not her spirit and aim wonderfully congenial with the spirit and aim of a modern medical school? What is needed for the training of physicians and surgeons to-day? I answer, first, science; secondly, science; thirdly, science. If two or three generations ago medicine was, on the side of theory, pretty much where Harvey had left it in the Seventeenth Century and, on the side of practice, scarcely in advance of that of Celsus or Galen, the last half century has wrought an entire change. As Sir Joseph Lister recently said, in his presidential address before the British Association for the Advancement of Science, "the practice of medicine in every department is becoming more and more based on science as distinguished from empiricism." Recall only the discovery of the functions of the spinal cord, of reflex action, of anesthetics, of the antiseptic method, of the germ theory of disease; think only how the prolongation of life and the lowering of the death-rate (in the City of New York from 32.2 to 19.5 in forty years) has been effected by scientific hygiene; enumerate only such instruments as the stethoscope, the ophthalmoscope, the laryngoscope, the pleximeter, the cardigraph, the spirometer, and the sphygmograph; consider the significance of these essential facts of the healing art of to-day and you will agree with me that modern medicine has been "scientificized." Now I do not claim that Cornell University has in any special way contributed to this transformation of empirical into scientific medicine. But I do assert that from the day of her origin she has observed the change, welcomed it, and endeavored to give her students the training necessary for the understanding of and participation in it. And so to-day she says to every one of these students, master your sciences or you never can be a physician or surgeon worthy the name. As Huxley once put it in an address to the students of my *Alma Mater:* "I do not believe that all the talking about, and thinking of, medical education will do the slightest good until the fact is

clearly recognized that men must be thoroughly grounded in the theoretical branches of their profession." And these branches Huxley reduces to physics applied to physiology, chemistry applied to physiology, physiology and anatomy.

Some of you will say that it is impossible to master the scientific bases of medicine in the one or two years—at most two years—which the medical schools assign to those subjects. This is my belief, too. And so I say, take more time. But not only for mastery of your sciences. A man educated merely in the sciences of Nature, a man whose mind has not been opened, elevated, and enlarged by art, letters, and philosophy is a good deal of a Philistine. Liberal culture, like virtue, or religion, has its own intrinsic value. I shall not, however, stop to argue a thesis so manifest and so universally accepted. But I do desire to ask you if it is not true that a liberally educated man—a man whose powers and faculties have been disciplined, chastened, strengthened, and enlarged by letters, philosophy, and science—will not have a great advantage over the man of mere professional education even in the practice of his profession. He will have deeper insight, a greater comprehensiveness and versatility of intellect, a surer faculty of seeing things as they are and disentangling what is irrelevant and sophistical. This is what gives such profound truth to the saying of Jowett—the greatest educator of his generation—that to be a good engineer a man must be more than an engineer. And I find this same sentiment among the most distinguished physicians. You will find it expressed in Sir Morrell MacKenzie's essay on "The Relation of General Culture to Professional Success" And the celebrated Dr. Stokes, a generation ago, laid it down as a maxim that "We must trust far less to the special than to the general training of the mind." My own observations and reflections as an educator and a student of the human mind have led me to the same conclusion. Generally stated, my view is that the mind in order to know anything well must know far more than that thing—and the more extensive and intensive that "more" is, the better will the narrower specialty be understood and the readier will be the power of applying it. I have had striking confirmations of this principle in my intercourse with professional men. The leader of the American bar once told me that he owed his success in his profession to his college work in philosophy and the languages. The Nestor of American journalism assured me that whatever reputation he had achieved was due to his college training in classics and mathematics. And as I scan the biographies of the men who were eminent in the medical profession, I find that Harvey devoted five years to academical studies at Cambridge before he went to Padua to study anatomy; that Richard Bright studied philosophy under Dugald Stewart; that Sir James Y. Simpson was a student both of mathematics and ethics; and that Sir Joseph Lister took his A. B. at the University of London five years before he came up for his medical degree. To every prospective medical student I should like to say, Go thou and do likewise.

Undoubtedly this will make large demands upon the time of the student. Now it is not necessary that any young man should be a physician or surgeon; but if he decides to become one he should aim at nothing less than the first rank. Here, too, as at other points, Cornell University will give him aid and encouragement. In our Academic Department the student has absolute liberty in the choice of studies. So that if our future medical student enters that course he may, without neglecting letters or philosophy, master thoroughly his anatomy, physiology, histology, chemistry, physics, and botany, and at the end of four years receive his A.B. degree. There then would remain of the medical curriculum only the professional branches, which he could compass in the next two years in New York City. Thus, thanks to our elective system, he would win both the A.B. and M.D. degrees in six years—though each separately requires four years.

It will then be to the advantage not only of the University and its Medical College, but of the student and the general public, if the relationship between the Academic and Medical Departments become closer and more constant. I hope to see it the rule for our students of medicine to spend four years at Ithaca in the study of letters, philosophy, and science—the latter covering in a thorough way the theoretical parts of the medical curriculum—and then two years here for instruction in the practical part of the curriculum, for which this great city offers unsurpassed opportunities. This Faculty of Medicine would, I am sure, rejoice if this arrangement were the general and normal one. Our Founder would rejoice, for his aim is not to attract numbers, but to offer superior training for those, be they few or many, capable of receiving it. And if along with this ideal of high intellectual standards we entertain a just conception of the inherent nobility of the medical profession—whose aim now and always is to discover and use the laws of Nature for the benefit of mankind—we shall, in this new college which we now open, erect a temple whose foundations are truth and whose superstructure is charity and philanthropy. And upon it and all its members I reverently invoke the blessing of God, who is at once both Truth and Love.

WAR ARTICLE.

SANITARY DIARY OF THE PORTO-RICAN CAMPAIGN.

By JOHN McG. WOODBURY, M.D.
MAJOR AND CHIEF SURGEON, U. S. V.; SANITARY INSPECTOR AT PONCE, PORTO RICO.

THE following order, which was issued by Major-General Miles, just previous to the landing of the army in Porto Rico, shows the admirable wisdom and forethought to which his command owes its good health, and the avoidance of a repetition of the sad scenes at Siboney and Santiago, in Cuba.

Headquarters of the Army,
On Board U. S. S. "Yale," en route
for Porto Rico, July 23, 1898.

General Field Order No. 2.

PAR. I. In order to prevent, as far as possible, the introduction of yellow fever into the command now about to land on the island of Porto Rico, the following will be strictly observed:

1. All persons connected with the army are forbidden to enter any building whatever on the Island without special authority from these headquarters, and all buildings and rural districts that may be suspected of harboring the germs of that disease should be destroyed by fire or thoroughly disinfected. No natives, except authorized guides, and those having permission from these headquarters will be allowed to enter camp.

2. As woven goods, particularly those of woolen fabrics, are special carriers of disease, the purchase or acceptance of articles of this kind from stores or inhabitants of the Island is strictly forbidden, and any such property found within the lines will be at once destroyed and the holder subjected to punishment. Commanders of regiments and of battalions will prepare their camp-grounds with great care and maintain a rigid police in them. Under no circumstances will they camp on ground that has previously been occupied by troops or by collective bodies of inhabitants. They will require medical officers to make frequent inspections of the commands to which they belong and all suspicious cases of fever will be isolated immediately, and the fact of occurrence reported to these headquarters.

3. Canteens should be filled daily with tea or coffee, and these beverages used habitually instead of water, unless that has been previously boiled.

II. An officer, to be designated hereafter, will take command of the base of supplies, and is hereby authorized to indicate the sites to be occupied by the various supply departments and hospitals, and will enforce the regulations governing the health of the attaches of these departments, and all persons who may visit them on business, or otherwise.

III. A sanitary inspector will be appointed from these headquarters, whose duty it will be to examine all vessels and persons arriving at our base from other ports or places, and who will prepare sanitary regulations for the government of all transportations and of persons arriving and departing from the station by land. He is hereby authorized to quarantine all suspicious persons and means of transportation and to disinfect their belongings either by fire, or by such other means as may be deemed necessary.

IV. All persons, whether soldiers or civilians, who may be captured, will be taken to a camp of detention, to be located at a point isolated from the general camp and no communication allowed with them, except through persons specially designated by the officer in charge.

V. Under no circumstances will a regular foraging upon the country be allowed. Whenever it may be necessary to procure supplies of grain, provisions, horses, etc., the foraging party will be in command of an officer, who will treat all well-disposed inhabitants with careful consideration, and will in every case pay cash or give a properly signed receipt in duplicate in lieu thereof.

V. This order will be read and re-read until each commanding officer is satisfied that every person of his command is thoroughly familiar with its provisions.

By command of Major-General Miles.

J. O. GILMORE,
Brigadier-General, U. S. V.

I was appointed by General Miles to the Sanitary Inspectorship of the Island in accordance with the terms of this order. Immediately afterward I inspected the jail at Ponce. This is the common "calaboso" into which the felons great and small are indiscriminately crammed by the Spanish authorities, and is situated just in the rear of the City Hall. It is built of brick covered with stucco on the outside. Its plan is that of a parallelogram, twice as long as broad, enclosing a central court, the space from the inner wall, or walk of the court, to the outer wall being roofed in flat tile upon which sentries were constantly posted. The inside was arranged like a cloister around the four sides of the parallelogram. It was dark and as profoundly filthy as only a Spanish prison can be, and the odors were beyond description. The lavatories and sinks were in an unbelievable condition. The criminals, being herded together like animals, were filthy to a horrible degree and were covered with vermin. Many were afflicted with loathsome skin diseases.

The caserne or barracks which had been so hastily abandoned by the Spanish troops of the 25th Battalion of infantry were in an equally filthy condition, the drain being choked and the place alive with vermin. This is a large, finely constructed building, having quarters for 500 men and officers. Well and solidly built, with no wood but the doors, it was easily disinfected and cleaned. The Spanish military hospital, which is a fine building one year old, having four wards and accommodations for about 400 men, is located upon a high hill at the outskirts of the town. It is thoroughly drained, and we were indeed fortunate to find such a hospital ready to hand. But its drain was choked, and the two wards which were then occupied by Spanish sick were filthy. The lunatic asylum was but a little, cramped road-section house, built for the shelter of the peons working on the highway between Ponce and San Juan. It was as filthy as all the other public buildings, and its wretched inmates covered with vermin, were cared for by two male

attendants. This den, as explained to me, was but a reception hospital for patients, later on to be transferred to the central asylum at San Juan.

The camping-ground of our troops was on a plain north and east of Ponce, an old sugar-cane field, the soil a black alluvial deposit of volcanic detritus washed from the hills by the Rio Portugese.

Finding the city to be without any health organization, I summoned, through the *Alcalde*, R. Ulpiano Colom, a clever and most able man and a pronounced American sympathizer, all the medical practitioners of the district of Ponce to meet me and organize a board of health. They chose for their representative Dr. Moret, who graduated at the Bellevue Hospital Medical College, New York, in 1880. He, with his Honor, the *Alcalde* of Ponce, and the syndic, ex-officio, now compose the Board of Health of Ponce. The board has charge of all matters of municipal sanitation and the Street Cleaning Department, as well as condition of water-supply. The three members composing the board then chose four inspectors, one for each of the wards of the town. These were *medicos titulares*, or "doctors of the poor." The rules for their direction, translated into English, are as follows:

I.—The Inspector will examine each day the district to which he is appointed.

II.—He will report each day its general sanitary condition:

a. Condition of streets, their cleanliness, presence of refuse, garbage, or waste paper, etc.

b. All odors from vaults, privies, cesspools, etc.

III.—The sanitary condition of the factories.

IV.—The condition of the slaughter-houses, whether clean, odorless, and the method of the destruction of its refuse.

V.—The condition of the market, whether clean or filthy, any negligence on the part of the vendors, and the cleanliness of their respective stalls and tables.

VI.—The condition of the public schools, their water-closets and floors, and general sanitary condition.

VII.—Where suspected, from odors, that the privy-vaults are in bad condition they shall be inspected and the result of the inspection communicated at once to the Board of Health.

VIII.—The condition of the yards and stables connected with the houses in which horses, cattle, or other animals are kept.

IX.—The livery-stables, their condition, the disposal of their manure. The diseases of horses that are contagious.

X.—While all physicians are required at once to report to the Board of Health any contagious diseases, as by list (diphtheria, smallpox, yellow fever, typhus, scarlet fever, measles, and chicken-pox), the inspector is required to examine any such cases in which any doubt may exist as to diagnosis, and his judgment is final.

XI.—The medicos titulares shall immediately inform the board of any of the above disorders occurring among the poor in their charge. The inspector will examine the case and order it to the proper hospital, or quarantine the sick in their own house if in his judgment it be proper.

A number of copies of these rules were given to each of the medical men in Ponce, and the substance enforced as accurately as possible. The immediate questions pressed upon the members of the board, with whom I meet three times a week, were:

1. *Street Cleaning*.—This was immediately began, and in some districts has been carried on quite well and will be pushed.

2. *The Public Water-Supply*.—This is derived from the Rio Portuguese. The intake of the aqueduct is about three miles from the city, at a pond formed by a dam about six feet high across the river. This pond has been almost filled by silt and the deposits caused by the wash of the heavy rains. It has been arranged to have the pond cleaned thoroughly and scraped out and another heavy galvanized iron strainer placed over the intake. The members of the 1st Regiment U. S. Volunteer Engineers are arranging detailed plans for a filter-bed to be constructed at the city terminus of the aqueduct before it branches or empties into the small reservoir that is built at its city end. This will be a great improvement, as in times of heavy rain the water is greatly loaded with earth.

The valley of the Rio Portuguese, which I have carefully inspected, is clean and only occupied by infrequent coffee estates, the drainage from which is inconsiderable. The purchase of a filtration-plant was recommended by the Health Board, but the emptiness of the city treasury preventing, the Engineers were applied to, with marked success.

3. *The Disposition of the Dead*.—The method at present in use must be immediately changed. The cemetery is in the town and is surrounded by dwellings. The dead of the wealthier classes are put into catacombs built above the surface of the ground and securely bricked up, and the entire tomb covered with a stucco surface. The public dead are buried in tiers in the ground, one on top of the other, and in a few years the ground is dug up again, the bones remaining being thrown out and the same space used repeatedly. This has been stopped, a proper site chosen for a new cemetery, the purchase money voted by the town council, and a proper place for the decent disposition of the dead arranged. The small cemetery at the Port of Ponce, used for the burial of our soldiers who have died in hospitals, is totally improper and insufficient. Some action should be taken by Congress at once to provide a suitable place for their interment. I have heartily endorsed the idea of the disposition of all dead by cremation, and am certain that in this extreme climate, and in the circumstance of so much sickness as accompanies the army of occupation, that I am right, and that cremation is the proper method for the disposition of the dead. This, however, meets with no approval from church, chaplains, or the sentimentalists. The climate renders the keeping of a body a danger and an offense, and all I have been able to enforce, so far, has been to hasten the interment.

What has been accomplished, so far, is the thorough disinfection with bichlorid of mercury and sulphur fumigation of the city prison, its cleansing by scrubbing and by whitewash, clearing of its drains, rebuilding of its sinks and latrines, and enforcement of cleanliness among its inmates. The floors and sleeping platforms are being rebuilt at present. The Spanish military hospital has been cleaned and fumigated twice, drains taken up and cleaned, and sinks and latrines rebuilt. This hospital has been the general military hospital at Ponce, and now, with its tentage extensions, is the central hospital for collecting the patients from surrounding commands. The having at hand such a building, and the rapid and efficient work of Surgeon-Major Daily in cleansing it under great pressure of necessity, has proved a great aid to the medical arm of the service.

The caserne, or barracks, which is now fit for use and is occupied by a detachment of the 19th Infantry, has been most thoroughly fumigated, scrubbed, and cleaned; the sinks have been rebuilt, drains cleaned, and the place rendered suitable for occupation. This will provide a most adequate shelter for the 400 troops necessary to garrison Ponce permanently, makes them comfortable and dry, and gives them the best hygienic surroundings. All captured woolen uniforms and clothing have been burned. Some bales of new cotton clothing having been boiled for an hour might be used, as they are sterile. No troops are quartered in buildings save the provost-guard on the roof of the jail, those in the caserne, and the provost-guard at Pleya, the port of Ponce, which is quartered in a lumber yard and sheltered by a shed. I have inspected the sheds which the Government has used at Pleya as storehouses, and find them after their policing clean and fit for use.

The camps of our troops are dry and well drained, and I could only earnestly recommend the enforcement of the stringent order against the men drinking the water and filling their canteens from the streams where the inhabitants were washing their clothes. Under the able administration of Colonel Greenleaf there has been an accurate uniform attempt on the Island to arrange beforehand for any sickness. With such a careful hand at the helm there is little probability that a breakdown and overcrowding of hospital service will occur. Of course, there are worthless men everywhere and some of them disgrace our profession, but all I have met here on my daily round of inspection are hard at it trying honestly to carry out Chief-Surgeon Greenleaf's orders, and, fortunately, we have been so supplied that there is no want either of cots, medicine, or food. In the general hospital good native cooks have been hired and are at work. They seem to do well. Of course, the general hospital is not to be compared with any of our best at home, but it is clean, the food is plenty and good, and it is most efficiently managed.

THERAPEUTIC NOTES.

Anytin and Anytol.—LOEFFLER (*Therap Monatshefte*, July, 1898) describes the properties and uses of anytin, a new chemical compound containing carbonic acid, oxygen, and hydrogen, 16.5 per cent. of sulphur, and 4.5 per cent. of ammonia. It is a brownish-black, very hygroscopic powder, making a clear solution in water in all proportions. It is precipitated from its solution in water by solutions of an alkali, similarly to the formation of soaps. Its chief value lies in its power to make soluble in water substances which are ordinarily not so. Hence, many substances which have had as disinfectants only a limited value, can be used in much stronger solutions than heretofore, and so made more effective. Anytin itself is not a strong disinfectant. It has not been found to contain living germs, but spores of different kinds may remain in it without losing their vitality.

A one-per-cent creasol-anytol solution has the disinfectant worth of a three-per-cent. carbolic one. All spores were destroyed in thirty-six hours in a ten-per-cent. creasol-anytol solution, whereas a five-per-cent. carbolic solution requires sometimes as many as sixty hours to destroy anthrax bacilli. For the preparation of catgut he recommended that the gut be allowed to remain in a ten-per-cent. solution for thirty-six or forty-eight hours and then preserved in alcohol. In this manner the gut was not injured in the least, although a week's soaking materially lessened its strength. A three-per-cent. solution has very little effect upon the skin, and a ten-per-cent. solution none at all. Tampons saturated with a one-per-cent. or two-per-cent. solution, and introduced into the nostrils and kept there for three or four hours, sufficed to limit the formation of crusts, and removed almost entirely the disagreeable odor of ozena. A three-per-cent. solution is recommended in the local treatment of diphtheria.

Quick Cure of Erysipelas.—SCHULTZE (*Therap. Monatshefte*, July, 1898) saw an erysipelas develop in the skin of the right hand of a patient who was recovering from a cellulitis of the member. The local and general characteristics of erysipelas were all present, and the trouble was spreading rapidly. Owing to the favorable situation of the trouble an old method of treatment was revived, an attempt being made to limit the further spread of the germs by the injection of a three-per-cent. carbolic solution into the skin all around the arm. Care was taken to make the injections solely in the substance of the skin, according to the infiltrating plan recommended by Schleich. Inside of three hours the patient felt decidedly better, and there was a fall of two degrees in his fever. On the next day the pain and fever had entirely disappeared, and the swelling subsided the day following.

To Relieve the Pain of Burns.—

℞ Cocain hydrochlorat. . . . gr. v
Camphoræ carbolat. } aa . . ʒss.
Ol. olivæ }

M. Sig. External use.

The cocain is to be thoroughly dissolved in the carbolate of camphor before adding the olive oil. Intensely painful burns are said to be quickly relieved by the application of this mixture.

SATURDAY, OCTOBER 8, 1898.

WOUNDS OF THE HEART.

The fact that the late Empress of Austria was able to walk some distance and go on board a steamer after receiving a fatal wound of the heart (for the necropsy showed that the heart had been completely penetrated) has been the occasion of no little surprise. The *Lancet* points out the fact that there are in medical literature records of survival of considerable duration after small heart wounds.

According to the *Supplemento et Polyclinico*, August 20th, and quoted by the *Lancet*, a remarkable case of penetrating wound of the heart occurred this past summer at Rome, Italy. On July 9, 1898, Dr. Parlavecchio reported to a medical society at Rome a case of punctured wound of the heart in which he had operated eight hours after the infliction of the wound, and saved the patient's life. The patient, a man twenty years of age, two days previously was stabbed with a knife in the fifth intercostal space, in a vertical line midway between the border of the sternum and the left nipple. He afterward walked to the hospital, a distance of 218 yards. Five hours later he was found to be suffering from pneumothorax on the left side, with extensive effusion, probably of blood, into the pleural cavity; the area of cardiac dulness was increased; at the apex the heart sounds were confused, and at the base they seemed distant; the pulse was irregular, intermittent, and small. Dr. Parlavecchio suspected a wound of the heart, or at least a wound of the pericardium, and proceeded to operate as soon as possible, although delayed in his preparations till eight hours after the injury. Chloroform was given and a free incision made in the fifth intercostal space, through which much blood escaped on opening into the pleura. Upon resection of the fifth rib a wound admitting two fingers was found in the pericardium. This was enlarged to expose the heart, in which a V-shaped wound, one and one-half inches long, was discovered near the apex, penetrating obliquely the left ventricle, and intermittently discharging blood. Four interrupted deep silk sutures were applied, which completely controlled the hemorrhage. The pericardial and intercostal wounds were then sutured, the entire procedure lasting forty minutes. The V-shape of the wound was probably due to the movement of the heart during the infliction of the wound, and the survival of the patient during the eight hours preceding the operation is explained by the occlusion of the heart wound by a clot. No clot was found there, but it may have been displaced by the struggles of the patient during anesthesia. The subsequent history of the case was uneventful, the patient insisting on leaving the hospital August 14th, five days after the operation.

A PLEA FOR JEJUNOSTOMY.

The relative unfamiliarity of even widely experienced surgeons with this operation, is sufficient excuse for discussing it from the theoretic standpoint of medical needs, rather than surgical attainments. The establishment of a more or less permanent fistula into the alimentary canal is justified by one of two necessities: the introduction of food and the outlet of feces. The most rudimentary physiologic study makes it plain that the former purpose cannot be satisfactorily fulfilled by an opening lower than the upper part of the jejunum; while the latter purpose would be defeated by the abstraction of needed nutriment and water if the opening were higher than the lower part of the ileum, although

circumstances may demand the establishment of an artificial anus at a higher point, for purely mechanical ends, notably the relief of intra-intestinal tension. Because of anatomic difficulties, fistulæ are not applicable to the esophagus and scarcely to the duodenum. Even if a fistula can be made into the duodenum, physiologic reasons contraindicate such an operation, from the propinquity of the pylorus and of the ducts of the two large tributaries to the intestine, namely the liver and pancreas. In a sense, this is an anatomic objection but it is so on account of physiologic processes, not on account of operative difficulties. Thus, an alimentary fistula affords a choice only between the stomach and the jejunum.

The real value of this operation has been overlooked. We can get a clue to its proper employment by considering: (1) the successful case of Hahn's in which physiologic rest of the stomach afforded by the jejunal fistula allowed the esophagus and stomach to return to a practically normal condition after two weeks; (2) the experience of various surgeons in cases of intestinal tuberculosis treated by entero-enterostomosis, and (3) the well-known postponement of death from ineradicable rectal cancer, by the establishment of an artificial anus. Senn and others have reported almost miraculous cures of intestinal tuberculosis by short-circuiting the affected part and allowing it physiologic rest. The withdrawal of the irritation of feces from a rectal cancer has often deluded the patient into a belief that the growth had become quiescent, and life has been prolonged just in proportion to the delay of the growth of the malignant focus. Why is it that it has never been seriously considered that the withdrawal of irritation from a gastric cancer is just as good treatment as the same principle applied to other cancers at an ineradicable stage?

Gastrostomy is a perfectly proper operation for cicatricial or perhaps syphilitic stenosis of the esophagus, and should, doubtless, be preferred to jejunostomy in all such cases in which the condition of the stomach allows a choice. But when the obstruction of the cardia is malignant, all that can be said in favor of this operation is that it prevents the patient from starving to death immediately. In the first place, it is contrary to the principle of side-tracking an inoperable lesion to allow a cancer of the cardia to be irritated by peristalsis, hydrochloric acidity, the impact of food-particles and the various organic irritants that are produced even in the preliminary stage of the most perfect digestion. Secondly, there is certainly not more than one chance in five that a stomach with a cancer at the cardia will be able to perform proper digestion or even prevent improper fermentation. There is a very prevalent idea that it is possible to apply one disease-name to almost every diseased stomach, but, as a matter of fact, it is very rare to find an organ which has only one disease. With cancer of the cardia we should rather expect deficiency of secretion, both of hydrochloric acid and later of the ferments, so that malfermentation would result; in many instances, this secretory disturbance would be not merely functional but the mark of a gastritis; dilatation of the stomach of moderate degree is quite common with stenosis of the cardia. I have seen —and certainly every surgeon and pathologist must have had much greater experience in the same line— the fistula itself involved in an extension of the malignant disease of the cardia. Thirdly, a gastric fistula in cases of cancer of the cardia not only allows irritation of the growth and faulty digestion but it is responsible for introducing toxic material into the intestine and thereby not only depressing the system but directly interfering with intestinal digestion. The toxic material has two sources, the cancer itself and the improperly digested food. The stomach is not a particularly valuable organ but, like some persons, owes its reputation for importance to its capacity of making trouble when it is disturbed. Not only the recent observation of patients from whom the entire stomach has been removed but similar experiments on animals and the study of cases of gastric failure in which motility remains good, have demonstrated that the bulk of the digestive processes falls to the intestine and its tributaries. If the stomach is not normal, it is far better to insert the food directly into the bowel than to pass it through a cavity that can only add to its irritating qualities. Thus, jejunostomy should be the operation of choice in all cases of malignant disease of the cardia.

When cancer of the pylorus has progressed beyond the possibility of a radical operation, gastro-enterostomy is almost universally conceded to be the desideratum. But the same arguments that have

been adduced against allowing food to enter the stomach when the cardia is affected with malignancy, apply *a fortiori* to cases of pyloric cancer. Especially is it to be noted that while, in cancer of the cardia, there is a general tendency to achlorhydria, atonic dilatation and catarrh, a pyloric growth of sufficient importance to call attention to itself must, almost necessarily, have produced stagnation, dilatation, and irritative catarrh of the stomach. To pass food through such a cavity when a clean, disease-free entry into the jejunum can be effected is contrary to all medical principles. Thus, it seems that gastrostomy and gastro-enterostomy should be superseded by jejunostomy in all malignant cases, unless some purely mechanical obstacle prevents a choice.

At this point, the student of internal medicine should leave the subject to the surgeon, it being the province of the latter to work out the operative details. But, as the operation is unfamiliar, even to many competent surgeons, and as certain practical operative procedures are necessitated by essentially physiologic considerations, I may be pardoned for considering the operation somewhat in detail. The first operations of jejunostomy consisted in making a simple lateral enterostomosis. These, however, allowed considerable leakage of food and great discomfort was produced by excoriation, or rather digestion, of the skin. In general any animal secretion causes more or less dermal irritation, but the digestive fistulæ are apt to be particularly troublesome on account of their bulk and digestive properties. The skin, however, is protected by its oily secretion, and pepsin is nearly inert as soon as the hydrochloric acid of the gastric juice is neutralized or organically combined. In most cases for which gastrostomy is performed, hydrochloric acid is reduced to a minimum. On the other hand, the jejunal contents consist largely of pancreatic juice, which attacks and splits fatty materials and which acts energetically on even raw proteids, in anything but a highly acid medium. Thus, the leakage from a jejunal fistula is almost caustic in its effects on the skin.

To obviate this difficulty, Maydl cut the intestine, implanted the distal end into the abdominal wound and made an end-to-side anastomosis between the proximal end and the efferent bowel. Albert made a side-to-side anastomosis and brought the kinked portion of the jejunum into the abdominal wound, making a second side-to-side anastomosis and narrowing the gut to form a fistulous entry. Karewski's modification seems the best and simplest of all. Briefly described, it is the same as Witzel's operation for gastrostomy, substituting the jejunum for the stomach and using, by preference, a silver cannula. The after-care of the case demands frequent feeding, with comparatively small quantities of nutriment and the physician should be consulted so as to insure a proper amount and proportion of the various kinds of food. All that the general practitioner can ask of the surgeon is that the latter operate on the jejunum instead of the stomach in the class of cases mentioned, and that the operation be such as to leave a water-tight fistula.

A. L. Benedict, M.D.

ECHOES AND NEWS.

Health of Troops at Honolulu.—Major-General Merriam reported to the War Department September 11th that he had inspected the kitchens and camps at Honolulu and found them in a sanitary condition and the health of all the troops very good.

Appointments at Bellevue Hospital.—The following appointments have been made to the university staff of this institution: Dr. Henry C. Coe, gynecologist; Dr. Geo. D. Stewart, surgeon; Dr. Egbert Le Fevre, physician; Dr. L. Bolton Bangs, genito-urinary surgeon; Dr. B. Farquhar Curtis, surgeon.

Dr. Pepper's Successor.—The faculty of medicine of the University of Pennsylvania, at a recent meeting recommended that Dr. James Tyson of Philadelphia be given full and general direction of the branch of Theory and Practice of Medicine, and that Drs. John H. Musser, Alfred Stengel, M. Howard Fussell, and Frederick A. Packard be appointed to deliver, under Dr. Tyson's supervision, the didactic lectures pertaining to the subject.

No Rest for the Ashes of Columbus.—The often-disturbed remains of Columbus are to make at least one more move. He was buried at Valladolid, Spain, but was soon after transferred to Seville. Thirty years later his remains were removed to Santo Domingo. When that island was abandoned to the French, these sacred relics were taken to Havana, Cuba, and now they are going back again to the country of his adoption, which he honored so highly.

New President of the Wistar Institute of Philadelphia.—Provost Charles C. Harrison, of the University of Pennsylvania, has been elected to the Presidency of the Wistar Institute of Anatomy and Biology, made vacant by

the death of Dr. William Pepper. Although the Institute is not a part of the University of Pennsylvania, it is under the control of its trustees. Its funds are held under a separate charter, and it is governed by a board of nine managers, six of whom are elected by the university trustees.

New York State Medical Association.—The chairman of the Committee of Arrangements of this association reports, in connection with the meeting to be held in New York City, October 18th, 19th and 20th, that the usual reduction in railroad fares to one and one-third fare for the round trip has been secured to the members of the association and their families, provided one hundred persons avail themselves of the privilege. The usual certificate and endorsement attending such an arrangement will be insisted upon. The committee has also completed arrangements for a banquet on the evening of October 19th. More than one hundred have signified their intention of being present.

Metallic Sinks for the Army.—One result of the study of camp conditions is the recommendation of a metallic-lined sink, sixteen feet in length, two feet wide, and eighteen inches deep. A water-pipe is connected at one end and a waste-pipe at the other. The trough is to be filled daily with water in which lime is to be placed. The trough is cleaned by flushing it through the waste-pipe into a covered sink or into movable receptacles which can be dumped at properly selected places. It is recommended also that similar movable sinks be constructed and placed on wagons. The whole apparatus can then be moved daily and the contents of the trough deposited at the appointed place. These wagons can accompany an army on the march.

Surgical Instruction at the University of Pennsylvania.—On account of the illness of Dr. John Ashhurst, the general supervision of surgical instruction has been given to Dr. J. W. White, formerly Professor of Clinical Surgery, and didactic lectures in this branch will be given by several of the younger members of the teaching staff. Dr. Henry R. Wharton, Demonstrator of Surgery, and Dr. Alfred C. Wood, Instructor in Clinical Surgery, are being considered as probable appointees. About two months ago Dr. Ashhurst was stricken with apoplexy at his home in Overbrook. He survived the shock, and his intellect is now clear and his judgment good. He would be able to carry on his work but for the attending paralysis.

Sanitary Conditions at Manila.—An officer on the staff of General Greene, writing August 9, 1898, says: "The weather has been very bad for the past few days; it has rained constantly, the ground is full of moisture, and everything is damp, wet, and nasty; the humidity is very great all the time. We are very comfortably situated, having a house about twenty feet square, which is raised from the ground about two feet. The men are fairly comfortable and are in shelter-tents raised above the ground from eighteen to thirty-six inches. They make a bed of bamboo and pitch the tent on top of it. The health of the men is excellent and their morale is very high. There are no mosquitoes here and not many bugs and we have seen no snakes as yet. The camp is about midway between Cavité Point and Manila."—*Army and Navy Journal.*

Medical Schools of New York City.—The College of Physicians and Surgeons and the University and Bellevue Medical School began their winter's sessions on Monday, October 3d. At the latter institution, Dr. Edward G. Janeway, dean of the faculty, addressed all the students in the large lecture-room. He outlined the courses for the year and said that the class of 1899 will be the last to be graduated in the three-year's course. After that the course will be four years. The class entering this year is the largest in the history of the college. The sessions will be conducted in the new building at Twenty-sixth street and First avenue. The Cornell University Medical College inaugurated its existence by public exercises held in the main amphitheater on Tuesday evening, October 4th. President Schurman of Cornell University made a formal address (see page 462). Dr. Wm. M. Polk, dean of the faculty, followed with some remarks in behalf of the faculty. After the public exercises an impromptu reception was held. The school opens with about five hundred students in attendance, most of them from out of the city.

Yellow Fever.—The United States Marine Hospital Service makes the following report concerning yellow fever, from July 20 to September 29, 1898:

Place.	Date.	Cases.	Deaths.
Louisiana:			
Baton Rouge	Sept. 25	1	—
Franklin	" 24	106	5
Harvey's Canal	" 24	6	—
Houma	" 22	1	—
Jefferson Parish	" 24	5	1
New Orleans	" 17	1	—
" "	" 20	2	—
" "	" 21	1	—
" "	" 24	2	—
" "	" 28	6	1
Wilson	" 26	12	—
Mississippi:			
Edwards	" 27	1	—
Jackson	" 27	9	2
Orwood	" 27	67	3
Oxford	" 27	13	4
Taylor	" 27	82	8
Waterford	" 9	1	—
Water Valley	" 28	1	—

Later advices indicate a steady advance of the disease in certain localities. October 2d, Jackson, Miss., reported twenty-two cases with three deaths to date. Detention camps are being established at various places.

The Mississippi Valley Medical Association.—The twenty-fourth annual meeting of this association will be held October 11, 12, 13, and 14, 1898, in the Capitol at Nashville, Tenn. Provisional program. First day, morning session, 10 o'clock: Address of welcome; reports of officers and committees; executive business; president's inaugural address. Papers: "The Relations of the Gyn-

ecologist and the Neurologist," W. H. Humiston, Cleveland, O.; discussion opened by C. H. Hughes, St. Louis, and Jos. Price, Philadelphia, Pa.; "Diagnostic and Therapeutic Uses of Tuberculin," Chas. W. Aitkin, Flemingsburg, Ky.; "Immunity," Chas. T. McClintock, Detroit, Mich.; "Hygiene *versus* Drugs in Pulmonary Tuberculosis," Charles L. Minor, Asheville, N. C.; "Some of the Factors That Predispose to Tuberculosis," L. P. Barbour, Tullahoma, Tenn.; "The Bicycle from the Medical Standpoint," I. N. Love, St. Louis, Mo.; "Therapeutic Value of Marmorek's Serum," W. L. Baum, Chicago, Ill.; "Tumors of the Parietal Lobe of the Cerebrum," T. A. Davis, Chicago, Ill.; "Unguentum Hydrargyri or Blue Ointment Administered by the Mouth," Albert Bernheim, Paducah, Ky. Afternoon session, 3 o'clock: "Wounds of the Lachrymal Apparatus: Report of Operation for Restoration of Canaliculi Obliterated by Traumatism," Geo. F. Keiper, Lafayette, Ind.; "Mastoiditis; When to Operate and How," Andrew Timberman, Columbus, O.; "Prophylaxis in Diseases of the Nose and Throat," J. Homer Coulter, Chicago, Ill.; "Three Anomalous Cases of Mastoid Disease," J. L. Minor, Memphis, Tenn.; "Report of Holocain as a Local Anesthetic in Ophthalmic Surgery," E. C. Ellett, Memphis, Tenn.; "Incarceration of the Iris Relieved by Eserin: Report of a Case," Frank Trester Smith, Chattanooga, Tenn.; "A Case of Bilateral Glioma of the Retina: Operation, Non-recurrence in Seventeen Years," A. G. Sinclair, Memphis, Tenn.; "Tonsillitis or Quinsy: Cause and Treatment," J. A. CORRESPONDENCE.

IODOFORM IN PHTHISIS.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In 1884 I began treating tuberculous patients with creosote, which was as much in evidence then as now, as a potent factor in the treatment of this scourge of mankind. I gave it in increasing doses so that 5, 10, and even 15 drops were taken three times a day. I was disappointed in every case in its efficacy. About 1893 I began to use strychnin, as recommended by Dr. Thomas Mays of Philadelphia, with apparently better results. It was administered hypodermatically to the physiological limit. Later I made a combination of strychnin, iron, and quinin. It then occurred to me to try to make, as nearly as possible, a local application to the diseased area of lung that thereby I might inhibit, if not destroy, the tubercle bacillus. Iodoform suggested itself as *the* drug for this important mission, iodoform being largely eliminated by the mucous membrane of the lung, so I added it to the above combination.

The results have been quite satisfactory in a rather large number of cases. No claim is made for it to cure advanced tubercular disease, nor to even mitigate *phthisis Florida*. But in incipient phthisis, when the patient begins to cough, accompanied by rapid pulse, pain in the chest, loss of appetite, and necessarily loss of flesh and strength, I have seen it act most advantageously.

I have never seen iodoform recommended in consumption, and in order that others may try it, and either prove or disprove the claim I make for its utility, is my chief object in writing this article. I began its use about eighteen months ago, and have given more than 2500 pills made from this formula:

℞ Strychnin sulphate . . . . gr. i
Reduced iron, Quinin sulphate, Iodoform aa . . . ʒij.

M. Ft. pil. No. XL. Sig. One pill after each meal.

Probably there is some incompatibility in this formula between quinin and iodoform, for the reason that not infrequently a patient will complain of pain in the stomach after taking a pill. I always speak of this to the patient and instruct him to discontinue taking the pills for a few days and then to begin again, being careful to keep the bowels well open. I have used the formula above mentioned with the quinin left out, and there was no complaint made of pain in the stomach, yet I doubt if with as good results as when the quinin was present. One drawback to the internal administration of iodoform is the disagreeable eructations which follow.

Yours truly,

E. L. DAWSON, M.D.

CAMDEN, ARKANSAS, September 25, 1898.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

OPENING OF THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA AND OF THE WOMEN'S MEDICAL COLLEGE—DR. TYSON CHOSEN AS DR. PEPPER'S SUCCESSOR—PERSONAL NOTES—COMPENSATION TO HOSPITALS BY THE GOVERNMENT—HAHNEMANN'S WOES — PATHOLOGICAL SOCIETY MEETING—FOOD ADULTERATIONS—HEALTH-BOARD STATISTICS.

PHILADELPHIA, October 5, 1898.

PROVOST CHARLES C. HARRISON formally opened the 1898-99 session of the Medical Department of the University of Pennsylvania in the chapel of the college building last Saturday, October 1st. He spoke briefly of the war, calling attention to the safety and immunity with which large bodies of men had been transported from the fever-infected locality of Santiago de Cuba to a camp near a large populous center, a feat which he considered greater than any victory obtained in battle. Dr. Pepper's death was alluded to, tribute being paid to his devotion to the welfare of the university and to his personal attainments. The provost promised on behalf of the trustees the speedy erection of new and enlarged laboratory buildings for the study of pathology, pharmacy, and physiology, plans of which were outlined in the MEDICAL NEWS last spring.

The opening exercises of the Women's Medical College were held Wednesday afternoon, September 29th, the regular college work commencing on Thursday.

Dr. Gertrude A. Walker, Clinical Professor of Ophthalmology, delivered the introductory address, in which she urged the adoption by medical colleges of a universal standard of requirements for admission equal to that required by the classical colleges of candidates for degrees. She also urged students to beware of the pitfalls of quackery, Christian science, faith cure, and mind cure, which owe their existence to the great prevalence of hysteria in our race and to the ills dependent thereon.

Dr. J. William White, Professor of Clinical Surgery at the university, will have charge of all instruction in this branch owing to the continued illness of Dr. John Ashhurst, Professor of Surgery. Didactic lectures will probably be given by Dr. Henry R. Wharton and Dr. Alfred C. Wood.

Dr. J. C. Da Costa, Jr., Assistant Surgeon Eighth Regiment, has returned home on sick leave.

Dr. Isaac C. Detweiler of Reading last week celebrated his sixty-eighth birthday and the tenth year in which he has donated all his fees to church and missionary work of various kinds, his latest contribution having been $225 with which to provide bibles for soldiers in Cuba and Porto Rico.

Five hospital ships with 800 soldiers on board are expected to arrive in Philadelphia this week and as most of the men will be taken care of by the various city hospitals there is some agitation over the question of compensation for this work by the government. While many, if not all the hospitals were led by patriotism and public spirit in offering their services, the constantly increasing amount of work has become a heavy tax upon the resources of

several and the statement that New York hospitals are receiving 93 cents a day for each soldier in their care has aroused a great deal of interest.

Secretary French of the National Relief Committee says there is no doubt as to the validity of a claim against the government for this work and while some few hospitals may refuse compensation there is to be a meeting next week for the purpose of deciding whether to accept remuneration and if so the rate per diem for each soldier.

Hahnemann Hospital physicians have been considerably stirred up over the alleged discrimination against this institution in the distribution of sick soldiers brought here by the various hospital-trains. Dr. Charles Mohr, a member of the Board of Trustees of the hospital, took occasion to bring this matter before the meeting of the State Homeopathic Society last week and stated that although the hospital had offered the use of twenty-five beds to the authorities when the first and second hospital-trains arrived but two soldiers were received. In reply the authorities having the distribution in charge say that every man on the trains was asked his preference and only two selected a homeopathic hospital.

Trouble has been brewing for the Hahnemann in another direction also and the State Homeopathic Society deemed it necessary to adopt resolutions expressing confidence "in the integrity and ability of the faculty of the Hahnemann College of Philadelphia and in the integrity and ability of our State Homeopathic examining board." The trouble, it is said, was caused by the refusal of the State Board to pass twenty-two graduates of this college last spring.

At a meeting of the Pathological Society held September 22d Dr. J. H. Jopson presented a chylous cyst of the abdomen which occurred in a woman aged fifty. The cyst, which contained about 200 cubic centimeters of chylous fluid, sprang from the retroperitoneal space between the kidneys, being firmly attached to the duodenum. Dr. H. L. Williamson presented a primary adenocarcinoma of the fundus uteri. The woman from whom it was removed by hysterectomy eighteen months previously, enjoys perfect health at present.

Dr. Henry Cattell presented a specimen from a case of gangrenous appendicitis. This occurred in a boy who had previously had appendicitis two or three times, the last attack which proved fatal having been induced by trauma.

Three of the crew of the British brig "Sunlight," from St. Kitts, were sent to the Marine Hospital last Friday, suffering from "logwood fever," a fourth having died last Wednesday.

Decisions were given this week in several of the civil and criminal prosecutions brought by the State Department of Agriculture against storekeepers for violation of the Pure-Food Law. A penalty of $100 was imposed on nine different counts against one dealer and several others paid penalties ranging from $100 to $500.

The total number of deaths reported at the health office for the week ending October 1st was 382, of which 113 occurred in children under five years of age. The number of new cases of contagious diseases was 300, reported as follows: Diphtheria, 128 cases with 30 deaths; scarlet fever, 15 cases with 1 death, and typhoid fever, 157 cases with 24 deaths.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

THE PROJECTED CHINESE UNIVERSITY AND SOME GERMAN ANTICIPATIONS — JAPANESE MEDICAL STUDENTS AT GERMAN UNIVERSITIES — AMERICAN MEDICAL STUDENTS ABROAD—THE QUESTION OF POST-GRADUATE MEDICAL INSTRUCTION IN AMERICA.

BERLIN, September 26, 1898.

THE recent official announcement of the Chinese Government to the Western Nations that she was about to formally open a Government University at Pekin, on the model of modern Western institutions, naturally attracted a great deal of attention in European university circles. China has learned from her little insular rival, Japan, the benefits of Western civilization. Her entrance into the educational field will be followed by an influx of Chinese into the European universities. If she imitates Japan in this as she has in most other things in her advance, the German universities will get the majority of her students who seek foreign parts. If the *number* of students who seek foreign instruction should bear any commensurate ratio to the comparative populations of the two countries then the Chinese students are apt to form an important factor in German university life in the early part of the next century after the savor of Western educational life shall have aroused some of the dormant appetite of the Celestials for modern culture.

At many of the German universities at present are to be found a select coterie of most intelligent, hard working students, some of them engaged in interesting original investigation, all of them doing solid work of the most important and fundamental character, who attract attention mainly by their retiring ways and thoroughly business-like attention to the matter in hand. They are the representatives at the university of the little Oriental island empire, that has attracted so much attention of late. Wherever an especially good course is being given, wherever particularly tempting opportunities for original work, or a special chance to follow closely the teaching of some maker of medicine presents itself, there Japanese students are to be found and usually in the immediate train of the master.

Kitasato's work with Professor Koch first attracted general attention and it was in bacteriology that the medical world first became familiar with the Japanese names. But now scarcely a volume of any important German periodical is without one or more contributions from Japanese medical men for the time being here in Germany, and some of them are the most striking articles of the volume. As a body, outside of the German students themselves, the Japanese constitute the most interesting feature of German university life, and one cannot fail to be struck with the evident purposiveness of their university work, and admire its results.

The system under which these results are attained is eminently worthy of consideration by those interested in

the development of medical education. After graduation in the Medical Department of the Japanese University, medical men who have distinguished themselves in their medical course as well as in the preparatory high school, are sent to Europe. Their preliminary education in the high school compares practically with that given in the German gymnasia, though less attention is given to Greek, so that they come to Europe with a breadth of mind and depth of culture well calculated to make them eminently receptive. They are sent to the German universities, exceptionally to others, at government expense, or at least with government aid.

These traveling scholarships are not hampered by too closely drawn relations. The special field of work is left to individual selection, and the place or places where it shall be pursued left to the student's choice, after he shall know enough of the medical situation in Europe to judge for himself. It is not expected that German methods will be mastered in a year or even two, at least three years being given to this post-graduate work, and sometimes five or more years. Japanese medical students are, as a rule, made readily welcome in German clinics and laboratories. There is beside the almost unconscious influence of the feeling of attraction for the quaint Oriental who has come such a distance for instruction, the knowledge that he is ready and willing to work, and that he will stay long enough to accomplish something and will not be interrupting his studies just when he has been trained to a point in observation where he might be able to prove his ability and enable his master to commend him with confidence.

Just the opposite state of affairs prevails to a great extent as regards American medical students and has made it, of recent years, more difficult for them than it used to be to get advanced work of a high order. Very few American medical students come to Europe for more than a year and those who do stay for two years have seldom contemplated so long a stay at the beginning and so their work has been arranged with the idea of departure after a year. As a rule, too, the American medical student who comes abroad has no definite idea as to what line of work he would especially care to take up, and has a number of other axes to grind. There is but a year abroad in his plans, yet he wishes to see London and perhaps Edinburgh for their literary and medical interest, he must see Paris and Rome for other reasons. His medical work he plans to do at Vienna or Berlin or both and usually he knows but very little German. Naturally not much really effective work is done, since there is no royal road and not even American dollars can pave a short cut, or American quickness and enterprise carry one quite to the Pierian spring of medical knowledge in a few short months.

At the end of the year scarcely more than the prestige of European study is gained, a smattering of German, sometimes of the most unsatisfactory character and a knowledge of German medical men's names and their faces that adds a passing interest to the perusal of German medical periodicals and literature. There is, of course, the broadening influence of travel, of association, and of contact even though but passingly with other methods and other ideas in medicine, that cannot fail to have its effect in after life, but compared to what might be accomplished by definite post-graduate work continued for two or three years, a minimum of good is done. Unless under exceptionally favorable circumstances it is only at the end of almost a year that the student is in a position to judge where and how he shall best secure what he wants.

Meantime, of course, there remains the interesting question as to when American universities and medical schools will seriously offer advanced post-graduate work, not only for their own, but for foreign medical students. In certain of the applied mechanical sciences Japanese students now go to some of the universities in the United States. In this matter the Chinese students will imitate them, I suppose, if our laws on the question permit it, unless our attitude toward the Chinese generally discourages them. The relations of China and Japan to Western countries generally are to be largely influenced in the future by the state of mind of educated men at home toward these countries. Opinions acquired during the plastic educational period in the midst of a people will remain, and the influence of German culture and the fact that the knowledge of the German language gives them their readiest view of European affairs through German spectacles, will always tend to draw the Orientals toward their old teachers the Germans in politics. In the present state of world politics, and the recent exhibition of German jealousy of the United States during the war, this is eminently undesirable. There is then a motive of patriotism in the matter that our recent entry into Oriental affairs makes extremely timely, and one cannot help but bewail the absence of effort in the matter.

Japanese feeling toward the United States as one learns it from the Japanese medical students here in Germany is of the most cordial character. There exists among the rising generation the sincerest admiration for the Western Republic whose rapid material advance and thoroughgoing, enterprising, business methods they would so gladly have their own rising country emulate. There is a sentiment in the matter then, that would draw these students to our shores for advanced medical work, if opportunities were but offered. With the advent of a new century, and the impulse that it should give to educational as well as other matters, it is not too much to hope that efforts in this direction will be made.

Recent expressions of German sentiment in our regard has made it even more desirable that Americans should find their post-graduate development at home, if possible. The inevitable entrance of the country into the world's politics makes it eminently to be desired that in educational development, as in everything else, there should be an independence that frees the country from any embarrassing foreign relations. The proper evolution of the patriotic idea is itself a function of this absolute independence in educational matters and constitutes an ideal to attain which unselfish effort some present sacrifices may well be made.

HYDROCEPHALIC CHILD BORN IN AN UNUSUAL MANNER — SUPRAPUBIC SYSTOSTOMY FOR PROSTATIC ENLARGEMENT — NEW METHOD OF SUPRAPUBIC CYSTOTOMY — POSTERIOR COLPOTOMY FOR PELVIC ABSCESS—SUGAR AS A DIURETIC — PERFORATING ULCER OF THE STOMACH — ACTION OF THE GASTRIC JUICE UPON TOXINS — TRANSMISSION OF TOXINS FROM THE FETUS TO THE MOTHER — CHANGES IN THE ORGANS PRODUCED BY SEVENTY-TWO HOURS ON A BICYCLE—PROCEEDINGS OF THE CONGRESS FOR THE STUDY OF TUBERCULOSIS IN MAN AND ANIMALS

At the Academy of Medicine, July 26th, Narich reported the case of a woman, aged thirty-six, who was in labor with her second child for fifteen hours when he was called to see her. The body and four limbs were already born, and examination failed to show any membranous spaces in the base of the skull, which was the only portion accessible to the finger. Attempts to apply the cephalotribe failed. Incision of the vertebral column allowed an enormous quantity of fluid to escape, and the hydrocephalic head was then born spontaneously. Examination of the fetal head showed a fracture in the occipital bone which made it possible for the contained fluid to escape in the manner described.

At the session of August 2d, Poncet spoke of the results of suprapubic cystostomy for prostatic enlargement, drawing conclusions from 114 operative cases. Eighty-seven of these patients recovered, 27 died. These cases may be divided into three groups, the first including 39 subjects without symptoms of infection or uremic poisoning. Only 2 of these died. The second group contained 29 patients with symptoms of uremic poisoning at the time of operation. Twelve of these died. In the third group were 46 cases with symptoms of chronic uremic poisoning. Thirteen of the patients in this group died. These figures show that the prognosis of suprapubic cystostomy depends upon the general condition; that is to say, upon the degree of uremic poisoning present at the time of operation. An early operation is therefore advisable. Some of the patients were striking illustrations of the advantage of this operation for prostatic enlargement. One of them who was operated upon at the age of 78, in the condition of coma, and with a temperature of 40.6° C. (105° F.), was alive and well 4½ years after the operation, being able to retain his urine for 3 or 4 hours during the day and longer at night. Another patient, 6 years after operation, was able to retain his water for from 3 to 5 hours, and then passed it in a stream through the hypogastric wound to the distance of 16 inches.

Suarez de Mendoza described at the session of August 23d a new method of incising the bladder above the pubes. The method commonly employed by dilating the rectum with a rubber bag is often the cause of temporary incontinence of feces and sometimes of rupture of the rectum. On the other hand, owing to inflammation, the distention is sometimes insufficient to accomplish the purpose of lifting the bladder out of the pelvis. To avoid these disadvantages the following method is recommended: The patient is placed in Trendelenburg's position, when a catheter passed into the empty bladder may be felt above the pubes below the reflexion of the peritoneum. It is cut down upon and serves as a guide for the passage of a thread before the bladder is opened. The catheter may also be utilized to irrigate the bladder immediately before the operation.

At the Surgical Society, July 20th, Richelot discussed the incision of the posterior cul-de-sac of the vagina for pelvic abscess, a method recently warmly advocated by Monod. While agreeing with the latter surgeon as to the advantages of this operation in suppuration of the broad ligament, or any abscess in Douglas' pouch not accompanied by lesions of the tubes or ovaries, he criticized in some respects Monod's optimistic views. It is difficult to determine whether the adnexa are diseased or not, so that in many cases an operation of this character will be of merely temporary benefit, and the patient will be left with a permanent fistula or, if this closes she may be subjected to the further devolopment of abscesses. In chronic suppurations, therefore, the incision of the vagina should only be performed to give immediate relief.

At the Medical Society of Hospitals, July 22d, Achard mentioned that polyuria often follows the injection into the tissues of a comparatively small quantity of sugar. This result may also be obtained by the ingestion of various sugars, but not so easily nor so surely. An appreciable effect has been produced by the injection of only 20 grains of saccharose; that is to say, about the fifth part of an ordinary lump of sugar. He proposes to use this remedy in cases of oliguria and has already done so in a few obstinate cases with good success.

Weil mentioned the fact that glycosuria of diabetes may disappear under the influence of biliary colic. He has twice observed this phenomenon. In both of these patients the sugar reappeared after the colicky pain ceased. Its disappearance resulted apparently from an inhibitory action upon the hepato-pancreatic centers. This action deserves to be classed with the reflex phenomena sometimes produced by crises of biliary lithiasis, which, as every one knows, are often accompanied by polyuria and glycosuria of a transient character.

At the session of July 29th, Galliard told of a woman, aged 36 years, who had for a year signs of ulcer of the stomach. Suddenly there came a feeling of intense heat in the left side of the abdomen, followed by vomiting, meteorism, and the signs of acute peritonitis. Two weeks later there was in the epigastrium a swelling giving a deep sonorous percussion-note, and the sound of succussion. The tympanitic-note extended to the base of the left side of the thorax, and the sound of succussion was heard in this situation behind, the respiratory murmur being abolished in that region. There was no amphoric breathing, nor any metallic tinkling. A longitudinal incision made at the summit of the epigastric swelling gave exit to a great quantity of fetid gas and pus. The abscess cavity contracted rapidly and in a month the wound had entirely healed. It was supposed that the perfora-

tion of the stomach which had given rise to this abscess, had cicatrized at the time of operation.

CHARRIN gave the Biological Society, July 30th, the results of his investigations of the action of the gastric juice upon toxins. It has been shown that the gastric juice as well as the juice of the intestine diminishes the power of diphtheria toxin. It digests it in other words just as it would any other albuminous substance. . A similar result is obtained if one mixes tetanus toxin with pepsin and dilute acid, and preserves the liquid for 24 hours at the body temperature. The toxin is also weakened by an exposure to bile and pancreatic juice. It is necessary to conclude, therefore, that the digestive juices have an important protective power against disease. This property may explain in part the power usually ascribed to the gastric and intestinal mucous membranes to resist the entrance of bacteria. At any rate it is easy to understand that gastro-intestinal troubles by altering the secretions in the alimentary canal predispose to the entrance into the system of microbes and their toxic products. The defensive mechanism is undoubtedly a complex one, but it is reasonable to suppose that these juices have at least as much power in the body as they have in a test-tube.

At the Academy of Sciences, August 8th, CHARRIN spoke of the transmission of toxins from the fetus to the mother. The facility with which toxins can pass from the mother to the fetus is well known. But the reverse of this process is equally possible. This was shown experimentally upon rabbits. A female was opened a short time before the birth of her young, and 1 c.c. of diphtheria toxin was injected in divided doses into the intestines of four of the young, their placentæ being avoided. In seven experiments of this nature, intoxication of the mother was produced, due to the passage of the placenta by the microbial products of the fetus. If a less virulent substance is used the injections may be several times repeated. By using sterilized cultures of pyocyaneus Charrin was able to render 3 out of 11 mothers relatively immune.

If then, poisons can pass from the fetus to the mother the same might take place when they were deposited in the fetus not by injection but had their origin in the father. From this results the interesting explanation of the phenomena of telegony so-called. If the elements of the fetus received from the father are of such a nature as to send into the mother a poison which will permanently affect her tissue-cells, making them more like those of the father, it follows that future children by another father may possess the characteristics of the previous father which have been so impressed upon the cells of the mother that her offspring partakes of their nature.

A the session of August 29th, REGNAULT and BIANCHI described the changes in the organs produced by a seventy-two-hour bicycle race. The examinations to determine these facts were made with a phonendoscope upon the first, second, and fourth winners of the race, immediately after its finish and again some days later. The abdominal organs, and notably the spleen, stomach, and liver, were notably diminished in volume. The subcutaneous fatty tissue had suffered in like manner. These changes were due to the lack of sufficient food and sleep, and to the excess of heat and excitement. The thoracic organs on account of the excess of blood coursing through them lost scarcely anything in size. The continual movements of the legs and pelvis, had displaced upward the organs of the abdomen and to a less extent those of the thorax. The right lung, on account of the weight of the liver, was lifted less than the left. The organs below the diaphragm were raised from one to two inches while the heart was displaced upward for fully as great a distance. It is easy to understand, therefore, the advantages of cycling in ptoses, pleurisy, and a too vertical position of the stomach.

The Fourth Annual Congress for the Study of Tuberculosis in Man and Animals was held in Paris from July 27th until August 2d. At the opening session, MARTIN read a paper upon the disinfection of the dwellings of the tuberculous, which has increased in Paris very rapidly of late. Whereas in the year 1892 only 4000 lodgings were disinfected on account of tuberculosis, the number for the first six months of 1898 is over 7000. One has only to think of the character of the dwellings of the very poor, where a whole family lives in one room, and many persons often sleep in one bed, to see how great is the danger of infection. Spittoons have been distributed, and attempts have been made to have them used, with a little water in them, the contents to be each day destroyed, and the spittoons boiled. Each week the patient's underclothes are to be boiled and washed. Many difficulties have been met, some of the patients being so poor that they could not afford to make a fire to boil anything, and others not having any underclothing at all. These prophylactic measures were in general well received. In some instances they had the unfortunate result to cause the afflicted individual to be regarded as a pestilence and even to be driven from the house.

LETULLE spoke of the hospital accommodation for tubercular patients in the city. Accommodations have been increased and facilities provided for the treatment of such patients with air, repose, and superalimentation; but there is urgent need for the erection by the city of numerous suburban hospitals which shall be given up entirely to the care of these patients. From a prophylactic point of view it is absolutely necessary that patients suffering from tuberculosis should be removed from their surroundings and cared for hygienically in buildings constructed for the purpose. Then as far as circumstances will permit, all those who have the disease should be cared for in such isolated institutions.

The reports of different experimenters upon Koch's tuberculin T.R. agreed in denying its value. "Despite the care and the time which we have given to this subject," said ARLOING, COURMONT, and NICOLAS, "it has been impossible to verify most of the affirmations of Koch in regard to his new tuberculin. The different results obtained can only be explained by the instability of the product or variations in the virulence of tuberculosis or differences in the technic. We deplore the lack of details furnished from Berlin. Our investigations have all led to the conclusion that tuberculin T.R. has no curative nor

preventive value in tuberculosis experimentally produced." Leclerg, after an experience with the tuberculin upon tubercular human beings said that its curative action is practically nil; and that while it is less dangerous than Koch's first tuberculin, it is by no means absolutely innocuous.

Courmont tested the serum reaction in suspected tuberculous pleurisy, and found the agglutinating reaction present in ten out of eleven pleurisy patients who had the clinical signs of tuberculosis. In the eleventh patient there was no reaction, and this result was sustained by the absence of bacilli in the fluid while guinea-pigs inoculated with it failed to become diseased. In five cases of tuberculous peritonitis the reaction was present, while it was wanting in eight cases of ascites due to cirrhosis of the liver. The agglutination was likewise produced in eight cases of tuberculous synovitis, but it was less marked than in the cases of pleurisy and peritonitis. The proportions in which the tuberculous serum was employed were from 1 to 5, up to 1 to 20. If the proportion of serum to culture was less than 1 to 5, agglutination was produced with plain serum.

Calot described his method for the treatment of tubercular joints without operation. He begins by making an intra-articular injection of 30 to 150 minims of naphthol-camphor every two or three days. After eight injections have been made, they are followed by two or three injections of iodoform-ether and then the joint is put at rest in compresses for three or four weeks. This completes the cure. Of forty patients so treated, thirty-nine were cured. The other had had the trouble for five years, and as it did not yield to treatment, an arthrectomy became necessary. In almost a quarter of the cases, the patients regained the partial or complete use of their joints. Calot expressed the opinion that one ought to attempt to regain motion in a cured tubercular joint in spite of the almost universal opinion to the contrary.

In a paper upon the "Surgical Treatment of Tuberculosis of the Bladder," Desnos said that curative operations such as curetting and resections usually gave no relief but resulted in the rapid spread of the infection throughout the urinary tract. The painful forms of tuberculous cystitis often render a suprapubic cystotomy desirable, but one ought not to attempt the removal of tuberculous patches from the mucous membrane, no matter how easily this could be performed. If the patient will consent to the maintenance of the fistula for a year or more, the pain will entirely and permanently disappear, and often the lesions themselves will remain stationary because of the relief afforded by the absence of congestion of the bladder and the cessation of the act of micturition. When every operation is contraindicated, it is necessary to have recourse to instillations of sublimate, or to injections of oil containing guaiacol, and to insist on the measures which will improve the general health.

Boucharde and Claude reviewed the methods which have been employed to utilize the Röntgen-rays in the diagnosis of tuberculosis. In conclusion they said that the radioscope was able to furnish invaluable knowledge of tubercular processes, but that the technic of the matter is extremely delicate and requires experienced observers, and favorable conditions. When so employed the method is able to give evidence of tuberculosis which cannot be detected by other methods of investigation. Thus Kelsch, who examined 124 soldiers who did not give evidence of tuberculosis by the ordinary tests, found by means of the radioscope that 51 of them probably had pulmonary lesions. In other cases of bronchitis and convalescent grippe the radioscope is able to show the integrity of the apices. The radioscope is also of value in showing the functional power of the lung, and it furnishes in all cases a fixed measure of the extent of the lesions for future comparison. Because of the difficulties of technic it will never be in the hands of every one, but rightly used it will prove one of the greatest aids in diagnosis, supplementing the facts gained by the methods now in vogue.

Widal spoke of local tuberculosis in aged persons and heredity in connection with tuberculosis. Local tubercular lesions, whether bony or in the skin, are rare in advanced age, but when they do occur they do not differ from those seen earlier in life. He had observed a dozen instances occurring in patients of from seventy to seventy-eight years of age. In some of them the tubercular infection had remained latent a remarkably long time. One of them had had hemoptysis at twenty, but no further manifestations of the disease until just at the close of his life. Two patients aged seventy-eight, gave a history of tubercular submaxillary glands at the ages respectively of eight and ten years. After a quiet interval of nearly seventy years, the disease again broke out, thus showing that its virulence can be preserved in the human body for this great length of time. Two other patients showed a sort of retrograde heredity of the disease. Their children manifested its lesions long years before they showed any of the symptoms, which later developed in them.

REVIEWS.

The Determination of Sex. By Dr. Leopold Schenk, Professor at the Imperial and Royal University and Director of the Embryological Institute in Vienna. Authorized Translation. New York: The Werner Co., 1898.

With a work bearing the authority of the name of the director of the Vienna Embryological Institute for sale to physicians and laymen alike, the old "Marriage Guide," "Sexual Hygiene," and similar works usually found in the back row of the book-case, with their alluring chapters on "How to Have a Boy or Girl at Will"—these books, the favorites of our fathers and of our wicked adolescent days, must be relegated to oblivion. Perhaps this fate will not be theirs until Dr. Schenk's theory has been given the rigid test of practical results; for unless we are grossly mistaken, other recent writers have claimed that male offspring may be acquired by other means than by the obliteration of all carbohydrates from the mother's economy.

The gist of the theory propounded by the author under consideration has been mentioned in the Medical News

(July 30, 1898). Dr. Schenk believes that upon the nutrition of the mother depends the sex of the impregnated ovum: a woman whose tissues are in a state of perfect metabolism may produce males, while a woman whose tissues do not respond as well to their katabolic demands, is more likely to bring forth females. The urine Dr. Schenk regards as the index. A trace of glucose is held to be inimical to male progeny as indicating imperfect metabolism. Dr. Schenk corrects the diet until the urinary examination shows no further trace of sugar. The remainder of the book is taken up with a history of previous efforts to regulate sex in men and animals, and with a citation of cases which the author regards as a vindication of his theory.

We suggest that the theory be not applied until it is desired to influence the sex of the infants of multiparæ, for it might prove embarrassing to a young woman to have frequent urinary examinations demanded and her diet rigidly supervised for two or three months previous to her marriage for the purpose of influencing possible offspring.

DISEASES OF THE EYE. By EDWARD NETTLESHIP, F.R.C.S., Ophthalmic Surgeon at St. Thomas' Hospital, London; Surgeon to the Royal London (Moorfield's) Ophthalmic Hospital. Revised and edited by W. T. HOLMES SPICER, M.A., M.B., F.R.C.S., Ophthalmic Surgeon to the Metropolitan Hospital, etc. Fifth American, from the sixth English, edition. Philadelphia and New York: Lea Bros. & Co., 1897.

SINCE the appearance of the first edition Nettleship's text-book has occupied the first place as a student's guide. In this day of voluminous treatises and discursive handbooks the popularity of conciseness and accuracy is attested by the publication of a sixth edition. The work has been brought up to the most recent standpoint. A supplement on color-blindness and the practical examination of railway employees by Dr. William Thomson adds greatly to the value of the volume, which contains, in an appendix, a well-arranged ophthalmic formulary.

THE PHYSICIAN'S VISITING-LIST FOR 1898. Philadelphia: P. Blackiston, Son & Co., 1898.

THIS well-known visiting-list appears in its usual form. It is a convenient and compact little book of its kind.

ATLAS AND ESSENTIALS OF PATHOLOGICAL ANATOMY. By DR. O. BOLLINGER, Obermedicinalrat and Professor. Volume II. *Urinary Apparatus, Sexual Organs, Nervous System, and Bones.* New York: William Wood & Company, 1898.

WITH the present volume of *Wood's Medical Hand Atlases*, Dr. Bollinger's work on "Pathological Anatomy" is completed. The translator, whose name for some unknown reason never appears in these atlases, has accomplished his task in a satisfactory manner and has closely followed the German text throughout. The illustrations, as heretofore in this series, are superb and leave nothing to be desired. Altogether the work fulfils its purpose admirably and is a valuable addition to the ever-increasing number of books on this subject of medicine.

LECTURES ON THE THEORY AND PRACTICE OF VACCINATION. By ROBERT CORY, M.A., M.D., Cantab., F.R.C.P., London. New York: William Wood & Company, 1898.

THIS little book, comprising the results of the author's experience of twenty-two years of teaching and practising vaccination, would appeal to public health officials chiefly. It contains nothing new, but is filled with valuable statistical tables and compilations, which might be of especial value to those who are engaged in polemics with antivaccinationists.

THERAPEUTIC HINTS.

Acid Drink for Diabetic Patients.—

℞	Acidi nitrici	*m.* lxx
	Glycerini	ʒ v
	Aq. dest.	Oii.

M. Sig. To be taken during 24 hours; a small quantity at a time.

Aromatic Cod-liver Oil.—The following mixture is said to lose all odor of cod-liver oil, and to taste only of eucalyptus:

℞	Ol. morrhuæ	Oi
	Ol. eucalypti	*m.* lxxv.

M.

Formulæ for Employment of Chloral.—

1. Hypnotic potion:

℞	Chloral hydrat. . . .	gr. x–xxx
	Sodii bromidi	gr. xv–xlv
	Codein	gr. ½–¾
	Syr. amygdalæ . . .	ʒ ss
	Aq. dest. . . . q. s. ad.	ʒ iv.

M. Sig. To be taken at night.

2. For cardiac dyspnea:

℞	Chloral hydrat. . . .	ʒ ss–ʒ i
	Potassii iodi	gr. xv–xxx
	Syr. acaciæ	ʒ iv.

M. Sig. One teaspoonful every hour.

3. For convulsions:

℞	Moschi	gr. iii
	Camphoræ	gr. xv
	Chloral hydrat. . . .	gr. viii–xxiv
	Yolk of egg	No. i
	Aquæ	ʒ iii.

M. Sig. For rectal injection.

For Scabies.—

℞	Sulphuris sublimat. }	aa . . .	ʒ ss
	Picis betulini }		
	Cretæ preparat.		gr. xl

M. Ft. ungt. Sig. External use.

For Chloro-anemia.—

℞	Calcii phosphatis }	aa . . .	gr. viii.
	Sodii chloridi }		
	Sacchari }		

M. Ft. chart. No. i. One such powder four to six times a day.—*Moraczewski.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIII. NEW YORK, SATURDAY, OCTOBER 15, 1898. NO. 16.

ORIGINAL ARTICLES.

SHALL ABSORBABLE OR NON-ABSORBABLE LIGATURES AND SUTURES BE EMPLOYED IN HYSTERECTOMY AND SALPINGO-OOPHORECTOMY?[1]

BY CHARLES P. NOBLE, M.D.,
OF PHILADELPHIA;
SURGEON-IN-CHIEF TO KENSINGTON HOSPITAL FOR WOMEN.

THE solution of the question as to whether absorbable or non-absorbable ligatures and sutures shall be used in abdominal surgery must be sought in the practical experience of the active workers in this field. Theoretical considerations are of value, but are of minor importance in comparison with practical results, and this is especially true in a subject so well worked out as that under consideration. To make my contribution to this discussion as concise as possible I shall confine my remarks largely to my personal experience and to the considerations which have influenced me in my choice of suture and ligature material in the past.

During the first eight years of my work in abdominal surgery I employed non absorbable ligature and suture material, that is, silk and silkworm gut, exclusively. During the last few years catgut has been used more and more, and non-absorbable materials relatively less. My own results with non-absorbable ligature and suture material have been excellent. The usual objections to the use of silk ligatures are that the silk is liable to become infected and to form the focus of an intraperitoneal abscess, or to be the cause of intraperitoneal sinuses. The percentage of cases in my hands in which intraperitoneal abscesses or sinuses were due to the use of silk ligatures was extremely small, and for a number of years it was confined exclusively to an extreme class of cases of pelvic suppuration in which gauze drainage was employed. The last case of ligature sinus in my experience dates back more than three years.

To secure the best results with silk ligatures, certain definite principles must be followed. The silk ligatures must be sterile. This has been accomplished by the method of fractional repeated sterilization. The ligature silk must be fine. This I consider a *sine qua non*. If heavy pedicle ligature is employed, abscesses about the pedicle and ligature sinuses are inevitable in septic cases. This is partly due to the fact that it is more difficult to encapsulate heavy ligature than fine ligature, and not less to the fact that the temptation to include large masses of tissue in the ligature is irresistible when heavy silk is employed. If fine silk is used, it is essential to include only a small amount of tissue in the ligature, as otherwise the ligation is insecure. The devitalization of large masses of tissue by heavy ligatures and the difficulty of encapsulating these ligatures, explain the relative frequency of pedicle abscess and ligature sinuses when this method is employed. The use of fine silk, the ligation of small masses of tissue, and careful toilet of the peritoneum, including a careful washing of the pelvis with salt solution as the final step in the operation, will ensure a minimum percentage of pedicle abscesses and ligature sinuses when silk is employed. The question of drainage also has a definite relation to the infection of silk ligatures. Pedicle abscesses and ligature sinuses were more common in the old days when drainage was frequently employed. The use of the Trendelenburg posture, the protection of the intestines from infection by covering them with gauze, thorough hemostasis, and an intelligent toilet of the peritoneum, including washing of the pelvis with salt solution, have enabled us to abandon drainage in all but the most exceptional cases. This improvement in technic greatly lessens the liability of silk ligatures to infection.

Mention has already been made of the fact that the cases which usually yield pedicle abscesses or ligature sinuses were those of extensive pelvic suppuration. Non-absorbable ligatures gave trouble in another way in a different class of cases—hysterectomies when the cervix was amputated at or below the internal os. In these cases in the beginning I used silk ligatures for the uterine arteries and silk sutures to close the cervical stump. These sutures and ligatures gave no trouble for a time after operation, but in a number of cases the sutures in the cervix became infected from the cervical canal, and some weeks or months later caused cellulitic deposits or ligature sinuses in or about the cervix. My own experience in this class of cases was that of others, and showed the necessity of abandoning non-absorbable sutures about the cervix in hysterectomy.

[1] Read in the discussion on "Should Non-absorbable Ligatures Be Discarded in Gynecological Surgery?" at the Twenty-third Annual Meeting of the American Gynecological Society, held at Boston, May 24, 25, and 26, 1898.

My own use of silk as a ligature material was partly due to early training, and partly to the fact that the general results of those who used silk as ligature material appeared to be better than those who championed the cause of catgut, the inference being that infection from the use of catgut was the cause of this apparent difference in results. The older methods of preparing catgut would not stand the test of a bacteriologic examination, and so long as this was the case it did not seem to me that one could conscientiously make use of catgut within the peritoneal cavity. With the introduction of reliable methods for the sterilization of catgut, this objection ceased to exist, and I gradually made use of it as an adjuvant to silk, both as ligature and suture material in the peritoneal cavity. As silk had occasionally given trouble in suppurative cases and in hysterectomies, catgut was employed for ligatures and sutures about the cervix in this class of cases. Not trusting it wholly, in addition to the ligation with catgut, fine, silk ligatures were applied to the isolated ovarian and uterine arteries. This was done in septic cases after the washing out of the pelvis, and in none of these cases has the fine silk ligature given trouble. With the substitution of catgut for silk to close the cervical stump in hysterectomy, post-operative inflammation about the cervical stump ceased to exist. It is an interesting clinical fact that not a single abscess about the stump of the cervix has occurred among my hysterectomy cases. Secondary ligature sinuses about the cervix occurred in a few of the early cases, but since the adoption of catgut this complication has entirely disappeared.

I next substituted catgut for silk in sewing the peritoneal flap over the stump in hysterectomies, and in closing the peritoneal layer of the abdominal wound. Increasing experience added to my confidence in catgut, and gradually it has been substituted for silk as a ligature material in my abdominal work. At the present time it is the routine ligature material in my work, and it is my expectation that silk will be abandoned for this purpose. I still employ silk in appendicitis operations, to suture the bowel, and for other special indications, but believe that even this field for its employment will be narrowed in the future.

My experience with non-absorbable sutures in closing the abdominal wound has been large. In my earlier work the old method of through-and-through sutures of silk or silkworm gut was employed. This method was abandoned because of its imperfections, and especially because of the relative frequency of hernia resulting from it. In May, 1892, I began the use of tier sutures, using silkworm gut as the material for the buried sutures.[1] The first method employed was the use of interruptured sutures of silkworm gut, introduced through the aponeurosis of one side, through the rectus muscle and the peritoneum, and in a reverse way through these structures on the other side of the wound. These sutures were tied and cut off, and remained permanently buried in the abdominal wall. The remaining portion of the wound in the subcutaneous fat and skin was then closed with interrupted silkworm-gut sutures. At a later period, instead of this superficial row of silkworm-gut sutures, a continuous catgut suture was employed to close the cellular tissue, and an intracuticular catgut suture to close the skin. In 1897 I adopted a new method of closing the abdominal wound, and in a paper, entitled "A New Method of Suturing the Abdominal Wall in Celiotomy"[2] described the technic of this method, and also reported and discussed my experience with buried permanent sutures in celiotomy incisions, Alexander operations, and femoral and inguinal herniotomy. At that time, buried permanent sutures had been employed in 365 operations, with 8 suppurations. Since that date 107 patients have been operated upon, with two suppurations, making a total of 472 cases, of which 10 suppurated, or 2 per cent. Of these cases subsequent hernia has developed in two. In one, the original operation was done for a large umbilical hernia in a large fleshy woman. More than a year later, during an attack of the grippe, the line of union gave way. This is the only hernia which has come to my notice among the cases in which primary union was obtained, 462 in number. Of the 10 cases in which suppuration took place, one hernia has developed. The operation was done in this case for tubercular pyosalpinx and tubercular peritonitis. The abdominal wound suppurated, and the buried sutures were removed. This patient subsequently developed a hernia, and later died of phthisis.

What becomes of the buried permanent sutures in cases in which primary union is obtained, is the question of greatest interest. After employing silkworm gut as a buried permanent suture for six years I have still to make the report that they remain permanently buried in the tissues. Not one of these patients has reported to me that the buried sutures have caused suppuration, and although I have made careful inquiry among my confrères in Philadelphia, I have learned of no case in which this accident has occurred. Both from the stand-

[1] "Remarks on the Use of the Buried Permanent Suture in Abdominal Surgery," *Amer. Gynec. and Obstet. Jour.*, December, 1896.

[2] *Amer. Jour. of Obstet.*, vol. 35, No. 4, 1897.

point of obtaining primary union, and from that of preventing hernia, this method of closing the abdominal wound leaves little to be desired. The objection to the method is the length of time which it consumes. Depending upon the length of the wound, it requires from ten to twenty minutes, or even longer. This is a real objection to the method, and may induce me to adopt chromicized catgut to close the muscles and fascia. I believe this would give admirable results, especially if the principle of overlapping the fascia recommended by me were adopted.

Silkworm-gut buried in the abdominal wall seldom gives rise even to the slightest irritation. Shortly after operation I have known patients to complain slightly of irritation about the sutures, which, however, invariably subsided. In the Alexander operation, however, a number of patients have complained of pain greater or less in character in the inguinal canals, which persisted for a long time. In one patient, a highly neurotic woman, I cut down upon one canal and removed the buried sutures, after which the patient ceased to complain. This patient knew of the presence of the buried sutures, and, therefore, there is some question as to whether the removal of the sutures had a local or mental effect. In this operation I have abandoned the interrupted silkworm-gut suture, and adopted the continuous chromicized catgut suture as recommended by Edebohls.

My contribution to the discussion would be incomplete without some remarks upon the character and preparation of catgut, and the advantages and disadvantages of this suture material for ligatures and sutures in abdominal surgery. Having tried various methods of selecting catgut from that furnished by the instrument-dealers, and that by commercial houses for use in the Arts, for some time I have confined my purchases to that furnished by a New York manufacturer. It is very difficult to obtain catgut in which the standard of size is maintained. Most of the commercial catgut which I have been able to obtain has been very defective in this respect. Much of it also has been of little strength. The catgut already mentioned has proven fairly satisfactory in every way.

The cumol method of sterilization has been adopted, and has proven very satisfactory. If the process is carried out by a competent person, the results are very uniform, and the catgut is even stronger than before sterilization. It has the advantage also that it ties well, and that it is not spoiled if it comes in contact with water. This is especially valuable when catgut is used in plastic work, as it can be used with constant irrigation of the field of operation. Apparently the cumol has the additional effect of lengthening the time necessary for the absorption of the catgut. When chromicized catgut is employed, the method recommended by Edebohls has been followed up to the point of chromicizing and drying the catgut. It is then put through the process of sterilization by the cumol method. The cumol method has stood the test of bacteriologic examinations, and in my hands the very satisfactory clinical test that after having used it for several years I know of not a single case of infection or suppuration which has followed its use. These considerations strongly recommend this method for the sterilization of catgut. The objections to the method are that it is somewhat expensive, and that to prepare a lot of catgut requires the undivided attention of a competent person for a number of hours.

The objections formerly urged against catgut were that it was a source of infection, and that it did not afford security against secondary hemorrhage. The first objection can no longer be urged, because at the present time several reliable methods for the sterilization of catgut are well known. Hence, the second objection only need be considered. The long continued and increasing use of catgut by such men as Boldt, Edebohls, A. P. Dudley, Gordon, Mann, and Kelly in this country, and Martin, Olshausen, and Zweifel in Germany, not to mention others, is a practical answer to the assertion that catgut is an unreliable ligature material. So far as I know, every one who has had extensive experience with catgut not only continues to use it, but is broadening the field of its application. So far as my own individual experience is concerned, in not a single case have I seen hemorrhage, either primary or secondary, in which catgut was employed. It is well known, however, that secondary hemorrhage has taken place after the use of catgut, and it is a very practical question how most surely to prevent this serious accident. Some time ago a fatal secondary hemorrhage from the uterine artery occurred in Kelly's service at Johns Hopkins Hospital on the seventh day after the use of catgut. In this case, apparently after the absorption of the catgut ligature, the thrombus in the vessel was forced out by arterial pressure. Wishing to know the experience of some of those who have made large use of catgut from the standpoint of secondary hemorrhage, I wrote to Drs. Boldt, Dudley, and Edebohls. Dr. Boldt states that he uses catgut exclusively in all abdominal work except for suturing the intestines. He takes no precautions in tying the knot, except "to make three loops instead of two

as in the case of silk." Some seven or eight years ago he had a death from secondary hemorrhage, due to the slipping of a mass ligature of catgut, and another case about two and a half years ago. Since then he has discontinued the use of mass ligatures, and ligates each vessel separately, using very fine catgut. He states that in both the cases of hemorrhage only a double knot was made instead of a treble knot. Dr. Dudley states that he makes general use of catgut in his hysterectomies, and has done so for years; in fact, catgut is his routine suture and ligature material in all his work. He has no cases of secondary hemorrhage to report. He always ties three knots, and leaves at least half an inch of free catgut beyond the knot. Dr. Edebohls states that he has always been an advocate of catgut in abdominal surgery, and that he used silk only in his first three or four celiotomies. Subsequently he used catgut exclusively except in intestinal surgery, and now he uses catgut even for this purpose. He has no cases of secondary hemorrhage to report. The method of tying the knot is to make a single loop in the first tie, and a double loop in the second. The knot is described on page 10 of his article "What Is the Best Method of Making and Closing the Celiotomy Incision?" published in the *American Gynecological and Obstetrical Journal* for May, 1896.

The foregoing indicates that the risk of secondary hemorrhage from the use of catgut as a ligature material is slight, and that it may be reduced to a minimum by the intelligent use of ligatures. Undoubtedly the ligation of the isolated vessels affords the greatest security against secondary hemorrhage. The method which I have followed is first to use relatively light catgut as mass ligatures, and subsequently to place individual ligatures upon the separate vessels. In this way time is saved in the operation, and equal security is assured. Until very recently fine silk has been used for the ligation of the individual vessels, but it is my intention to substitute catgut for this purpose. In tying catgut I make a triple knot invariably, and in either the second or third tie make use of a double instead of a single loop. The free end of the ligature is cut off about a third of an inch from the knot.

Having considered the supposed objections to the use of catgut, it remains to mention the real advantages of this material. In my own experience non-absorbable sutures and ligatures have given almost no trouble. I have adopted catgut in the hope that it will give no trouble at all, and thus eliminate even the small percentage of ill results formerly encountered. We should at least aim at the ideal, especially if in doing so we lose no practical benefit by change in technic. It is certain that with care and intelligence intraperitoneal abscesses and intraperitoneal sinuses due to silk as a ligature material will seldom be met with; but with catgut as a suture material, if suppuration does take place, it is a satisfaction to know that the healing of the abscess or sinus will not be delayed until the sutures are discharged.

For the expert who has every facility at his command which the modern hospital affords, I think there can be no question that the absorbable sutures and ligatures offer distinct advantages over the non-absorbable. For the occasional operator, I question very much whether this is true. He is not likely to have a supply of sterile catgut, nor the facilities to sterilize it. His relative inexperience also in applying ligatures puts him at a disadvantage in using catgut, as undoubtedly more skill and patience is required to properly secure catgut ligatures than silk ligatures, therefore, except for the expert I am inclined to believe that sterile silk will give better results than catgut.

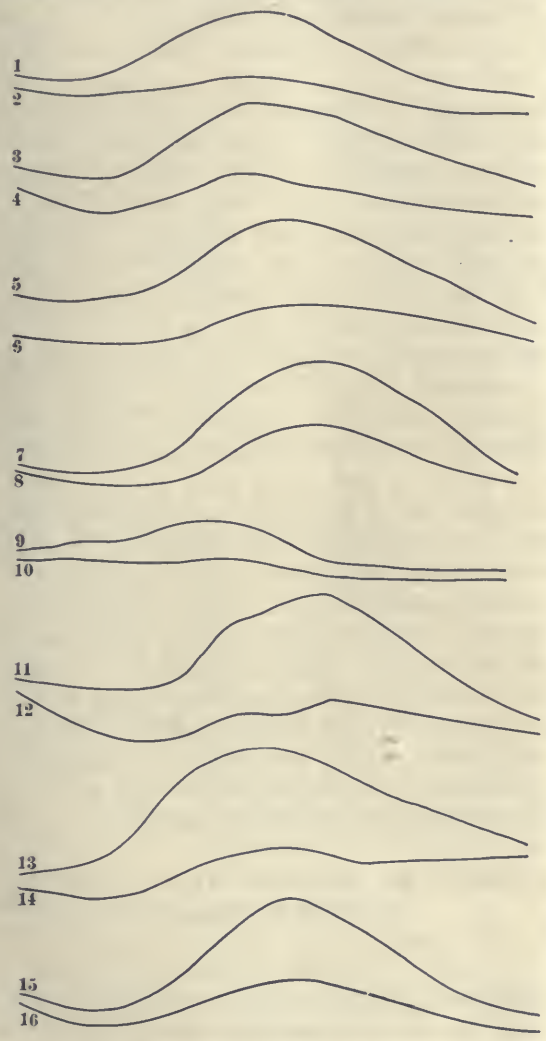
FORCIBLE STRAIGHTENING OF SPINAL CURVATURES.[1]

BY JOHN RIDLON, M.D.,
OF CHICAGO;
PROFESSOR OF ORTHOPEDIC SURGERY IN THE NORTHWESTERN UNIVERSITY MEDICAL SCHOOL.

THE immediate straightening of spinal curvatures by the use of considerable force is not a new procedure. Two thousand years ago the method was so old that the name of its author had been forgotten. The only new thing in its revival is that the patient is profoundly anesthetized during the operation. I made my first attempt at forcible straightening of the spine with the patient fully anesthetized on June 23, 1897. Since that time I have made the attempt in every case coming under my observation in which it seemed to me admissible, and in which, after fully explaining the operation and its results to the parents, permission to operate could be obtained. I think I have learned some things from personal experience, but there are still several points upon which I feel in more or less doubt, and it is these that I would be glad to have discussed. As to spondylitis: (1) Is there any risk to the patient except dissemination of tubercle and death from general tuberculosis or tubercular meningitis? (2) What additional percentage of risk is there from dissemination of tubercle? (3) Does the presence of demonstrable abscess or of a sinus add to the risk? (4) How much of a relapse, or return, of deformity must we expect during the subsequent treatment by recumbency and fixation-

[1] Read at the Twelfth Annual Meeting of the American Orthopedic Association, Boston, May 18, 1898.

dressings? (5) What are the best fixation-dressings during recumbency, and afterward? (6) Can we reasonably expect the gap between the carious bone surfaces produced by the operation to fill in and solidify with bony material so that relapse of deformity after the healing of the tuberculous process will not take place? (7) Will the period of treatment be prolonged or shortened by the operation, and about how long will that period be? (8) Is the use of an anesthetic an advantage or a disadvantage? As to



scoliosis: (1) Is there any risk in forcible straightening? (2) What degree of gain may reasonably be expected? (3) Can the gain from forcible straightening be maintained? As to rachitic curvatures: What may we reasonably expect from forced straightening?

On October 5, 1897, I read a paper on this subject before the Mississippi Valley Medical Association at Louisville, Ky., reporting the cases of the patients operated upon by me up to that time. The paper was not published, but was emended and amplified and again read on December 23, 1897, before the Chicago Medical Society. It was published, in abstract, in the February number of the *Chicago Medical Recorder*, and in full in the *Journal of the American Medical Association*, March 26, 1898. Altogether I have attempted the operation in 16 cases of spondylitis, 7 cases of scoliosis, and 1 case of rachitic curvature. One case reported in my October and December papers as scoliosis, and included here among the seven cases of scoliosis, I am inclined to regard as spondylitis because the mother died of tuberculosis; because the deformity, though lateral and posterior, was very great for so short a duration as two years; because the sensations communicated to the hands of the operator during the straightening were identical with those felt in straightening spondylitis and quite different from that in the cases of undoubted scoliosis; and because of the utter helplessness of the patient when the jacket was removed on account of an attack of typhoid fever eight months after the straightening.

I will not enter into the details of the cases already published, but those since December 23, 1897, are as follows:

Case I.—Female, six years old. Spondylitis; duration two years. Family history negative. Onset preceded by traumatism. Previous treatment various. Tracing No. 1 shows deformity present. There was an old sinus in the left loin. On December 28, 1897, the spine was straightened, as shown in tracing No. 2, and a plaster-jacket put on during horizontal traction.

Case II.—Male, ten years old. Spondylitis; duration seven years. Family history negative. Onset preceded by traumatism. Previous treatment by anteroposterior spine brace. The deformity present is shown by tracing No. 3. There was an undescended psoas abscess. On January 6, 1898, the spine was straightened, as shown by tracing No. 4, and a plaster-jacket was put on during horizontal traction.

Case III.—Male, six years old. Spondylitis; duration more than nine months. Family history negative. Onset preceded by traumatism. Previous treatment by an ill-fitting steel brace. The deformity present is shown by tracing No. 5. On January 8, 1898, the spine was straightened, as shown by tracing No. 6, and a plaster-jacket was put on during suspension by the feet.

Case IV.—Female, ten years old. Spondylitis; duration four years. Family history negative. Onset preceded by traumatism. Previous treatment by plaster-jacket for six months, when paraplegia came on; then recumbency and horizontal traction by weight and pulley for one year until the paraplegia had passed off; then anteroposterior spine-brace with chin support. The deformity present is shown by tracing No. 7. There was complete motor and partial sensory paraplegia, and the feet and legs were cold and blue. On January 18, 1898, the spine was

straightened, as shown by tracing No. 8, and a plaster-jacket including the head was put on during suspension by the feet. Immediately after recovery from the anesthetic the patient was able to move the limbs, and after twenty-four hours the sensation, color, and temperature of the limbs were normal. There was partial relapse of the paraplegia for which a second operation was performed on February 24, 1898, since which time there has been no paraplegia.

Case V.—Male, thirteen years old. Spondylitis; duration eight years. Family history negative. Cause unknown. Previous treatment various. The deformity present is shown by tracing No. 9. There was an undescended psoas abscess on each side. On April 13, 1898, the spine was straightened, as shown by tracing No. 10, and a plaster-jacket was put on during horizontal traction.

Case VI.—Female, five years old. Spondylitis; duration about two years. Family history negative. Cause unknown. Previous treatment by an ill-fitting steel brace. The deformity present is shown by tracing No. 11. The patient had had cough and indigestion for about two months. Uncertain diagnosis of pulmonary tuberculosis. On April 14, 1898, the spine was straightened, as shown by tracing No. 12, and a plaster-jacket, including the head, was put on during suspension by the feet.

Case VII.—Male, nine years old. Spondylitis; duration five years. Family history negative. Cause unknown. Previous treatment by a brace, applied by an instrument-maker, followed by an anteroposterior spine brace applied by an orthopedic surgeon. The deformity present is shown by tracing No. 13. There was an undescended left psoas abscess. On April 20, 1898, the spine was straightened, as shown by tracing No. 14, and a plaster-jacket was put on during horizontal traction.

Case VIII.—Male, five years old. Spondylitis; duration one year. History negative. Onset preceded by traumatism. Previous treatment by an ill-fitting steel brace. The deformity present is shown by tracing No. 15. On May 5, 1898, the spine was straightened, as shown by tracing No. 16, and a plaster-jacket was put on during horizontal traction.

The cases of scoliosis present nothing of sufficient interest to warrant detailed description. The youngest patient was nine years old and the oldest eighteen years; the shortest duration of deformity was eighteen months, and the longest seven years. In all the cases the deformity was reduced from one-third to one-half.

The patient in whom rachitic curvature was present was a male, seventeen years old, and the deformity dated from infancy. There had been no increase of the deformity for fourteen years. The operation was performed on January 13, 1898, and nothing was gained in the way of correcting the deformity.

Taking into consideration all of my cases of spondylitis, four patients had demonstrable abscesses, one had an old sinus, and one had paraplegia. No harm appears to have arisen from the abscess complication, or from the presence of the old sinus. The paraplegia appears to have been positively benefited. Two patients stopped breathing on being turned from the prone to the supine posture during chloroform narcosis, but both began to breathe again after a short interval; in one instance the plaster-jacket was cut open and allowed to gape an inch, and in the other it was not. Only one patient showed any elevation of temperature after the operation. In this instance disseminated pulmonary tuberculosis was suspected, but not proven. The patient's temperature was not taken before the operation, and consequently it is not certain that the elevation was due to the operation. In two instances it was not possible to straighten with what seemed to the operator a safe amount of force. Pressure sores under the plaster-dressings have been frequent. Their locations have been over the kyphosis, the scapular spines, the posterior iliac spines, and the sternum, and in various places about the head.

Relapsed deformity can usually be greatly reduced by a bearable amount of horizontal traction with backward bending over a foot-rest without an anesthetization. Only two patients have as yet been allowed to get up and walk around, one in a plaster-jacket, and one in an anteroposterior leverage spine brace. In no case as yet do I think I have obtained reliable bony solidification at the point of disease.

As to the cases of scoliosis, all the subjects were materially straightened and made taller, but all have lost part of the gain since the operation. It appears to me doubtful if a permanent straightening is maintained unless a reliable fixation-dressing is worn for a long time. Despite my failure above recorded, I am convinced that straightening of rachitic curvatures can be effected in younger patients.

SUPPURATING OVARIAN AND INTRALIGAMENTOUS CYSTS.[1]

By WILLIAM H. WATHEN, M.D.,
of Louisville, Ky.;
Professor of Obstetrics, Abdominal Surgery, and Gynecology in the Kentucky School of Medicine; Gynecologist to the Louisville City Hospital.

An ovarian tumor, as a result of torsion or twisting of the pedicle, may have the circulation cut off to such an extent that the life of the tumor is destroyed, so that gangrene, suppuration, and death ensues unless adhesions are so extensive as to furnish a sufficient supply of blood to the parts. As a rule, however, there are no extensive adhesions to the tumor when torsion of the pedicle has been sufficient to completely obstruct the circulation. The suppurating tumors of which I desire to speak are

[1] Read before the Louisville Clinical Society.

not the result of torsion of the pedicle, but result from the passage of pathogenic germs from the bowel through the walls of the tumor. It is sometimes stated that ovarian cysts, or cysts arising in the uterine adnexa, suppurate because of the passage of gas from the bowel into the tumor. I do not understand, nor can I appreciate, how this can occur from the passage of gas *per se*, and I believe that these suppurating tumors result from the passage of germs of suppuration, such as the streptococcus, etc., but more frequently from the passage of the bacillus coli communis from the bowel into the tumor.

I recently removed a suppurating tumor from a feeble old woman, which weighed about forty pounds. The patient's general condition was good, considering the size of the growth and the fact that it had existed for several years, and I was greatly surprised to find upon introducing a trocar to drain off its contents that it was purulent. The amount drawn off was five gallons. The omental and intestinal adhesions were so lightly attached that they were easily separated with a sponge, showing that the suppuration had so changed the character of the tissue surrounding the cyst wall that the adhesions were ready to drop off.

In an examination of the tumor since removal it appears that adhesions had existed over its entire surface, and one would believe that I had separated them from every part of the surface of the cyst. Such a peculiar condition resulted from the action of the infection upon the walls of the tumor, and when the intestine lying in contact with the cyst wall was separated, although it was not torn, it was so rotten that I feel sure had I not sutured it thoroughly in a longitudinal direction for at least three inches it would have ruptured and the woman would have lost her life. The patient gave no evidence of constitutional infection, and had no trouble after the operation, making a prompt recovery.

The infection evidently came from the cecum and the ascending colon where they were adherent to the cyst. I have removed several large suppurating tumors which were intraligamentous or retroperitoneal; they had extended under the bowel and had unfolded the mesorectum and the mesocolon, the muscularis of the bowel lying in direct contact with the cyst wall, so that the bacilli could pass from the bowel without having to penetrate the peritoneum.

Six months ago I removed a tumor containing three gallons of pus. This tumor had existed for ten or twelve years, and had been tapped many times by a doctor in Cincinnati. The patient had been under the observation of two of our general practitioners, and a month before I operated she was suddenly taken very sick, becoming unconscious and remaining so for several days. She had high fever and her general appearance and complexion indicated that she had pus somewhere in the system. The tumor was retroperitoneal, had opened the folds of the mesorectum and the mesocolon, and had to a limited extent invaded the mesentery of the small intestine, so that the surface enucleated was twenty inches in diameter. The tumor having suppurated, the toxins from bacterial growth caused the symptoms from which the patient had recently suffered.

From another woman I removed 1½ gallons of pus from a retroperitoneal cyst arising in the hilum of the ovary, which had also unfolded the mesentery of the colon. In a fourth case, in which I operated per vaginam, on the left side there was a cyst extending under the rectum and the colon, and nearly up to the umbilicus which had suppurated. On the right side there was an intraligamentous cyst extending nearly up the umbilicus which had not suppurated. In these four cases the infection resulted from the passage of bacteria from the adherent bowel, or from the bowel where the mesentery had been opened after a fashion that allowed the muscularis of the gut to come in direct contact with the cyst wall of the tumor.

The same method of infection I am sure applies to the following case: About two years ago I performed a celiotomy upon a young married woman from Owensboro, Kentucky, for the removal of a tumor in the left inguinal region, extending nearly to the umbilicus. She was so emaciated that she did not weigh more than seventy pounds, and had been an invalid for many months, but was not generally septic. The cyst was intraligamentous, had unfolded the mesorectum, and contained two quarts of pus. The inflammatory exudations had so firmly united the cyst wall to the capsule that no dissection could be made, and the opening in both the cyst and the capsule was sutured to the abdominal incision and the cavity drained. The cavity was irrigated twice daily with sulphurous acid one part to water ten parts, which prevented bad odor and very soon caused a healthy granulating surface, and the patient returned home in four weeks with the wound entirely closed and has had no further trouble.

Two years ago I was consulted by a woman from near Salem, Indiana, whose abdomen was enlarged by a tumor to the size of that of a pregnant women at term. She had been delivered of a well-developed child about two months before she was referred to me. The tumor had been diagnosticated before she was pregnant but apparently had caused no trouble during pregnancy. Her convalescence from the labor was protracted; she had attacks of

local peritonitis, had not been able to leave her bed, had become greatly emaciated, and her general appearance indicated a fatal prognosis unless she could be cured by surgical means. I diagnosticated an ovarian cystoma with extensive adhesions. The cyst was unilocular, adherent to intestines and omentum, and contained two gallons of pus. Before the operation her temperature was 103° F., and pulse 125, but she had no fever after the first day, and her pulse was normal after a few days. Her convalescence was uninterrupted, and she returned home in three weeks.

Referring further to the first case reported, it is unusual that a woman should have so much pus in her abdomen without its causing more serious systemic infection, but the toxins of suppuration seem not to have been absorbed into the system, as no symptom of septic poisoning was present. In none of these cases did the veins or the lymphatics carry pathogenic germs into the system, nor were the toxins absorbed in any but the second case, in which the tumor contained three gallons of pus. In none of the six cases was the peritoneum soiled with pus during the operation, nor was there the slightest evidence of infection following the operation, convalescence in each case not being disturbed. While no bacteriologic examination was made of the pus from any of the cysts, I believe it was sterile, the pathogenic bacteria having been destroyed, as so often happens in chronic cases with large accumulations of pus.

NOTES ON SURGERY IN THE RECENT WAR.[1]

By WILLIAM DUFFIELD BELL,
OF NEW YORK;
MAJOR AND SURGEON, 71ST REGIMENT, NEW YORK VOLUNTEERS.

On the morning of June 20th, the transports having on board the 5th Army Corps under General Shafter and designed for the invasion of Cuba, arrived off Santiago. During the following four days the entire force, consisting of about 13,000 men, was landed in two detachments, one at Baiquiri, a village on the coast about seventeen miles east of Santiago, and the second detachment at the small village of Siboney, a few miles nearer Santiago, and on the line of railroad running from the Juragua Iron Mines, near Baiquiri, to the City of Santiago. Siboney was chosen as a base of operations against Santiago, and here it was that the greater part of the Army of Invasion was collected. Throughout the hamlet were several hospitals for wounded Cubans, which were directly under the control of Cuban surgeons, and were located in houses and sheds all in a more or less insanitary condition. The wounded in these hospitals were the first met with in which the results of modern projectiles could be studied, and while but little regard had been paid to the rules of antisepsis, yet they furnished object lessons that proved of great value in the campaign that followed, by the variety of wounds and the effects produced by the bullet of the Mauser rifle, the explosive bullet used by the Spanish Volunteers and fired by them from the old-fashioned Springfield rifle; also, the bullet of the ordinary Springfield rifle, and the wound produced by the shrapnel used by the Spanish artillery. The surgical dressings used by the Cuban surgeons were of necessity of the most meager character, though much skill was often shown in the treatment of these cases, and it is not a matter of surprise that they should have used these houses for hospital purposes since the same error was committed by the surgeons of the American Army when the wounded Americans from the battle-field of La Guasimas, on the morning of June 24th, as they were brought in, were placed in houses under like unsanitary conditions, when the large, open sheds of the Juragua Railroad Company, on a slight elevation and near the seashore, would have afforded ample protection from the sun by day and the heavy dews by night. These sheds were afterward occupied by the 71st Regiment, New York Volunteers, who found them a very desirable place in which to be quartered. After the army had landed and advanced on its march toward Santiago, a large and well-equipped hospital was established at Siboney under Major La Garde, Surgeon United States Army, who, prior to leaving Tampa, had arranged his ambulance and hospital outfit in perfect working order, but through some mischance this outfit was scattered among several different transports, and the army was deprived of much that would have aided materially to the efficient services rendered by this officer. There was but one field hospital in the American army in Cuba, and this was established and maintained mainly through the determined efforts of Major M. T. Wood, Chief Surgeon of the 1st Division, 5th Army Corps. This officer, when he could not secure sufficient transportation for his hospital equipments, loaded his own horses and those of the medical officers with him, with all they could carry, and the three ambulances, which constituted the entire outfit of the army, and which were attached to his division, and in this manner, by repeated trips, moved his field hospital from Siboney to Savilla, a place on the trail leading to Santiago, and about seven miles from Siboney. This was the only halt made by the army after it left Siboney until the San Juan Hills were captured after the bloody battle of July 1st, and where the army

[1] Read at a meeting of the New York Academy of Medicine, held October 6, 1898. For discussion see page 507.

encamped from that date, until it was finally moved out of Cuba and returned to the United States.

Major Wood, June 30th, established his field hospital at Playa del Este, a small, open field about three miles distant from the San Juan Hills, and near the Aquadores River, in order that a plentiful supply of water could be had conveniently. Three large tents were pitched for operating purposes, while four or five similar ones were used as follows: one for the preparation of antiseptic solutions, and in this tent was placed a large filter, through which water, that had previously been boiled, was filtered. This was done in order to make sure that any soluble poisons might be destroyed, and all doubt as to the purity of the water used set to rest. Men were detailed for this purpose, and all the water used in the operations and in the dressings of the wounded was so prepared. Five additional operating-tables besides those in the operating-tents were placed in the open space in front of the tents, and were used by the surgeons, who were assisting the hospital staff, for minor operations, and upon which wounds of a less serious character were dressed. Another tent contained surgical supplies and drugs only. The other tents were used for wounded officers and for those cases of a serious character and which required extra amount of care. The capacity of this hospital was limited to the accommodation of 100 patients, and yet over 650 patients were treated here before dusk on July 1st, and upward of 400 more had been attended to before the night of July 2d. There was no scarcity of surgical supplies and dressings at this hospital. Large boxes containing these articles and sterilizers had been brought up from Siboney with great difficulty, but the supply was ample to meet the great demand made upon it during the three-days' battle. The hospital staff under Major Wood, the Chief Surgeon, consisted of five surgeons, several hospital stewards, and a Hospital Corps company of about twenty-eight men, selected from the hospital corps of the different regiments comprising the 1st Division. Of these, thirteen men came from the hospital corps of the 71st Regiment, New York Volunteers. Three ambulances, with one or two wagons, completed the outfit. Early on the morning of July 1st everything was put in readiness for the battle that was about to take place, and shortly after nine o'clock the wounded began to arrive from the dressing-stations near the front, and from that time on, for the next two days, there was a constant stream of wounded men coming in from all directions to this one place for relief. The surgical force of the hospital went promptly to work and worked rapidly and skilfully to meet the demands made upon it, but it proved insufficient, and when toward night the fire at the front slackened, five additional surgeons were called in from the firing-line to assist, and yet in spite of all their efforts numbers of the wounded lay unattended for twelve and even twenty-four hours on the bare ground before their turn came. There was an insufficient supply of blankets and clothes due to the lack of transportation facilities.

In the matter of clothes it was very important, for the clothes of many of the soldiers were soaked with rain and stiffened with mud from the trenches, so that they had to be removed before an operation or dressing, and could not be put on again. The transportation of the wounded was another source of much concern to the medical officers. The litters belonging to the different regiments and those improvised from various articles, such as blankets, blouses, hammocks, etc., and the horses of the officers were all that could be relied upon to remove the wounded from the battle-field. Men with desperate wounds had to walk or crawl a mile, or perhaps five or six miles from the village of El Caney, or the San Juan Hills, back to the field-hospital at Playa del Este, over a wild, rough country where trails were rendered almost impassable by daily rains and by the passage of pack-mule trains and heavy army wagons. It is not surprising that under all these circumstances the work of collecting and transporting the wounded should have been one of infinite difficulty. The great variety of wounds received during the battle of July 1st, on which day the majority of the casualties occurred, would have furnished a valuable addition to the annals of surgery could a complete record have been kept of all the cases. Men shot through the abdomen by the Mauser bullet were known to have walked four and five miles to the hospital and to have arrived there in good condition, with little or no shock, and to have recovered apparently with but little disturbance in the way of pain and without the necessity of resorting to an operation.

There were several instances to my knowledge of men who received wounds from the Mauser bullet that passed directly through the liver and kidney, and yet these men thus wounded suffered but little inconvenience and have apparently showed no bad results, though what may occur in the future is still uncertain. Another point of interest was that a Mauser bullet was apt to be explosive in its action when it struck a man at short range, and especially where a viscus, as the brain, or a joint was penetrated, and inflicted a wound similar to that made by the brass explosive bullet used by the Spanish Volunteers. At a greater range than 200 yards the Mauser bullet penetrated with but a small

wound of entrance and with a slightly larger wound of exit, and both decreased in size as the firing distance was lengthened. If beyond this distance bones were injured there was always more or less comminution and the wound of exit was a trifle larger, due to the laceration of the soft parts from splinters of bone. There were some cases in which the shaft of a long bone was fractured by a Mauser bullet passing through it, with but little splintering and a clean perforation. There were several instances in which the Mauser bullet passed through the skull and out again, causing no apparent injury to the brain and the patients returned to duty in a few days with the wound entirely healed. In another instance, at short range, a young man was shot in the head by a sharpshooter and the result was similar to that caused by the explosive bullet. This explosive bullet is composed of soft lead with a brass coating, and on impact explodes, leaving a ghastly wound. It was used by the Spanish Volunteers, as has been already mentioned, who fired it in the old Springfield rifles, and who, in order to make the action more deadly, would chew the end or cut small gashes in it with a knife, so as to insure its exploding if it came in contact with any obstacle. Its passage through the air was accompanied by a peculiar humming sound, ending in a short, sharp pop, as it burst and scattered fragments of lead in the air. The existence of this bullet was denied by many officers, but the effects have been observed under circumstances that left no room for doubt.

There were but few amputations and these were performed only when a main artery had been severed or a limb mangled by shrapnel. The simplest antiseptics were found to act best in dressing such cases and iodoform was almost entirely abandoned, owing to the fact that its use in the tropics was observed to cause irritation to the skin and that it was too readily absorbed by the exposed surfaces. In dressing small wounds collodion was much used. Laparotomies were performed in several cases and I believe were fatal in almost every instance. Nearly every officer and man in the regular service was provided with a first-aid packet, which proved of great value in rendering first aid to the injured, and many of the Hospital-Corps men carried haversacks filled with these packets, which they distributed along the firing line. The Volunteers were not well supplied with these and did not appreciate the great value of these packets and would often throw them away or use them for some other purpose entirely foreign to that intended. The dressing-stations near the firing-line were devoted entirely to the application of temporary dressings, the arrest of hemorrhage, and the setting of fractures, which was necessary in quite a number of cases, and much ingenuity was displayed in the dressing of these cases of fracture. Several bad compound fractures of the thigh were received at the field-hospital and these were dressed under the most careful antiseptic precautions and put up in plaster of Paris and sent by ambulance to Siboney for transportation to the United States.

The number of killed during this campaign is estimated at about 280 and wounded at about 1400. But a small proportion of those wounded (65 in all) died of their wounds and but a small number have required much additional care since their return to the United States.

The Medical Department of the army in Cuba, in spite of all obstacles in the way of scarcity of rations, difficulty in procuring proper transportation and supplies, met the emergencies as they arose and in the whole army there was none deserving of more praise than those members of the Medical Department, who risked everything in the discharge of their duty. Passing along the line of fire, being exposed at all times to the bullets of the enemy in front, and the more deadly and continuous fire of the sharpshooters on the flanks, the Geneva cross of each medical officer and Hospital-Corps man was a tempting mark which they never failed to take advantage of, as the murder of young Dr. Dantforth shows. This officer was shot down in front of a dressing station in the rear of the firing-line, and it is satisfactory to note that the sharpshooter who killed him met the same fate a few moments later.

PHYSICAL CONDITION OF THE FIRST UNITED STATES CAVALRY (ROUGH RIDERS) AT DATE OF MUSTERING OUT.

BY FRANK DONALDSON, M.D.,
ASSISTANT SURGEON, FIRST VOLUNTEER CAVALRY.

IT is difficult to judge at this time just what will be the outcome of the work of the Army Investigation Committee in Washington, but one fact has been emphasized by a number of witnesses before it, to wit, that the condition of the camps and of the men of the volunteer regiments, apparently without exception, left much to be desired. The blame in each case has been put upon the officers and the surgeons who failed to compel compliance with the more ordinary rules of cleanliness and health. Without criticizing the camps of other volunteer regiments which I have seen it may be interesting for medical men to know that up to date there has been no fault found with the condition of the camp or troopers of the First Volunteer Cavalry. Though the men

suffered terribly in Cuba from fever, dysentery, and serious stomach and intestinal troubles, no regiment came back in better shape, with the possible exception of the Ninth and Tenth Negro Cavalry Regiments.

In Cuba, of course, we were able to give the sick men anything but satisfactory care owing to an almost total lack of a hospital outfit; and in view of our experience both in Cuba and at Montauk I cannot but sincerely trust that the Surgeon-General will see fit to return to the old system of regimental hospitals. Many of our men in Cuba should have been treated in a well-equipped regimental hospital, but the division hospital was five miles away and it was practically impossible to send the men there against their will. They preferred to suffer and be among their own comrades at the front.

I wrote a long letter last spring to the *Philadelphia Medical Journal*, after some days spent with Dr. Girard at Camp Alger, in which I conclusively proved (?) that regimental hospitals should be done away with; experience has taught me that I did not know what I was talking about. I am sure to-day that had we had a proper hospital outfit in Cuba we would have saved much suffering and probably several lives. What we called a hospital was a large fly under which we put the men. We had no cots, insufficient supply of blankets and no rubber covering beyond the miserable government poncho which never protected any one from anything, certainly not from rain. The troopers, however, did have rather more and better food than most of the regiments. Thanks to Colonel Roosevelt's unceasing thoughtfulness for the men and his delightful contempt for red-tape where their needs were concerned, we were enabled to "rustle" quantities of food and stimulants. His private purse was always open and he often told me to stop at no expense in getting supplies of all kinds.

As I said, the regiment returned in excellent condition and with his permission we immediately established the despised regimental hospital. Here in the course of four weeks we treated upward of two hundred men and had the satisfaction of sending many of them back to their troops in fairly good shape. An interesting fact in connection with the low form of malaria with which most of those treated were afflicted and the stomach and intestinal trouble accompanying it, was that quinin, without any exception, brought on severe vomiting; and it may seem strange that in four weeks I did not personally give twenty grains of quinin. I did not have the proper preparation for hypodermic use, and should have hesitated to use it in any event. In many the vitality was so low and the circulation so sluggish that even a few minims of morphin given with an antiseptic syringe frequently lit up a subacute inflammation, and I am sure that the combination of quinin and urea would have caused troublesome abscesses. My efforts were directed toward getting their stomachs and digestive apparatus in working condition, and with this purpose in view they were fed frequently with small amounts of delicate nutriments. I used sherry and egg, port wine, milk punches, champagne, and other stimulants with absolute freedom. It should be remembered that most of these men had been for several months, while at Tampa and in Cuba, taking from 30 to 60 grains of quinin a day, and six out of ten men who came to the hospital were suffering from partial deafness, and all from more or less constant nausea and vomiting. I can give no better proof of the care which Colonel Roosevelt demanded for his men and which they received than the fact that there were only thirty men who were really too sick to come to Montauk to be mustered out. I make this statement advisedly, for I have a complete list of those who were not on hand when we finally broke camp. The actual number which did not come to be mustered out was 103, many of these, however, though physically able to get back, were delayed in returning from various causes. From the men not seen personally I have received letters regarding their condition, and after carefully examining my notes I am safe in making this statement. Of these thirty only twenty were ill, and at the present writing we have but four men seriously sick; these four with typhoid fever. This record is a source of considerable pride to us, for surely thirty ill men out of a regiment of 1200 speaks eloquently for the care which they have received.

As I said before, we could not have obtained this result had it not been for Colonel Roosevelt's constant help, moral and financial, and I can truthfully say that it is to his unselfish devotion, unceasing oversight and personal interest in every man, that this volunteer regiment has come out in such good shape. Moreover, his interest did not cease with the breaking up at Montauk. Acting under his orders the condition and position of every man, sick or in need, has been looked into by me and their necessities provided for. Of course, I do not mean to say that there were not men mustered out who were more or less sick; a number of them still have certain stomach and intestinal trouble, and occasional fever.

Its a curious fact that out of a certain series of eighty men whom I examined for mustering out, seventy-four had either enlarged livers or spleens. Another curious fact is that in three cases I found,

the men complained of a gradually failing eyesight, and on questioning them it appeared that the trouble began after they had been for four or five weeks at Tampa. None of the three men of whom I speak had been to Cuba. They were not suffering from any kidney trouble, nor had they had a sunstroke. In two of the patients, while they could distinguish objects, their eyesight for reading had failed completely. These two had been treated by experts in New York, and told me that they could then with effort read ordinary type and that their eyesight was gradually improving. The third soldier told me that he had gotten no better, and the specialist feared his eyesight was permanently gone. An instance of apparent transmission of the Cuban fever by infection from a fly-bite occurred after we were mustered out. A lady who was helping me nurse in the regimental hospital was taken a few days later with what proved to be a typical case of Cuban fever. I was absolutely at a loss to account for it. She had been perfectly well, had not been in a malarious district, and spent the summer in the North. During several days while at Camp Wikoff we had a terrible visitation of flies and the men in the hospital complained that their bite frequently drew blood and on several occasions the lady called my attention to the fact that blood had followed the bite of one of the flies. She is now in a hospital and the disease is running a typical course.

ADDRESS.

CORNELL UNIVERSITY MEDICAL COLLEGE.[1]

By WM. M. POLK, M.D.,
OF NEW YORK;
DEAN AND DIRECTOR.

There is a divinity which shapes our ends, rough hew them as we may.

HEREIN lies the explanation of the success which has attended the conception and creation of this medical school, and we who have been the instruments employed have but one feeling, an all-pervading feeling, especially on this the opening occasion of our educational work; and this is a deep sense of our responsibilities to our benefactor, our University, and to you. It might be supposed that the distinction, which these factors in our existence have bestowed upon us, would create an elation which would warrant a desire for the triumphal car and its attendant glories, but I know, that so far from this being the state of our minds, a spirit of seriousness possesses us, in keeping with renewed effort rather than effort accomplished. It is evident that this argues well for the execution of the trust placed in our hands.

In this wonderful country of ours a considerable number of men has been produced who through the exercise of natural powers upon the opportunities before them have acquired the means wherewith to bestow munificent gifts. With the thousands of impecunious enterprises continuously projected, it is evident that these men are never free from solicitation to contribute to this, patronize that, or endow the other. Hence it is scarcely to be wondered at, that more than the ordinary discrimination is needed to avoid bestowal in wrong direction and apply it in the right. When, therefore, after proper inquiry and deliberation, such a bestowal is made, it carries with it the obligation that the recipient shall in all things live up to the expectation of the benefactor. In the construction of any undertaking ideals may be priceless, and they are priceless if they personify the highest, installed upon a basis of common sense. Such ideals contribute working formulæ, and can, therefore, be readily used in promoting an undertaking; and the greatest good fortune attends upon the enterprise which possesses such an ideal and has at hand the means with which to reach toward it. It is doubly fortunate if, with the means, come hand in hand the ideal. You know we have the means, and infer we have the ideal, but you do not know that the same hand which bestowed the means unconsciously brought with it the ideal. For this gift was in reality a protest against intrigue and deception, and a proof that faithfulness is as essential to lasting success in the great things of life as in the smallest. And yet this was not all. It was not enough to give us this ideal, but a place in which to exercise and develop it in all its bearings was also given in putting us within the folds of a great university.

If you will go with me to the town of Ithaca you will there see grouped upon the hills overlooking the head of one of the most extensive and beautiful of the many lakes peculiar to the interior of this State, a wonderful sight: A great university, the result of thirty years of growth. And, questioning as to the source of such a development, we find the answer in the words of its distinguished President: "It lies in its 'constitutive idea.' Every college and university is an organ of the highest knowledge. Its function is the consecration of liberal culture. This was the accepted view held a generation ago, and it was deemed sufficient. Cornell University went further. It associated practical education with liberal. It ranked professional training among its functions, and it enlarged the notion of learned or scientific professions so as to include, along with the traditional trio of law, medicine, theology, whatever calling rests on science or scholarship." In the words of its founder, it is an institution "where any person can find instruction in any study." "Hospitable to all the learned and scientific vocations of modern times, it yet, at the same time, enlarges the conception of liberal culture so as to give the sciences of nature and the modern humanities a place beside the ancient discipline of Greek, Latin, and mathematics."

The eminently American character of the University is clearly defined in its democracy of liberal and scientific schools, and the vigor which characterizes its administration is perpetuated in the love and loyalty of its large classes, and the marvelous *esprit de corps* of its numerous and influential alumni. This is the inheritance we

[1] Delivered at the opening exercises of the College, October 4, 1898.

have been bidden to share, and in taking our place, do so with a deep determination to lend our minds and bodies to the fulfilment of its ideals.

As has been said, an essential part of this ideal is the practical, and herein lies the core of what we deem our duty to you, the students.

At the risk of wearying you with repetition of what you have already learned from our circular of information, I must say something of the manner in which we propose to meet the demand for the practical in your instruction. After a good many years devoted to medical education, we have arrived at the conviction that clinical demonstration upon a broad basis of laboratory instruction is the only way in which to prepare students for the degree of Doctor of Medicine. This has been forcibly borne in upon all undergraduate teachers by the universal demand for post-graduate instruction in details, without which a graduate is in reality unfitted for the practice of this profession. The first question that had to be answered related to the disposition of the didactic teaching, that part of the course which offered the preliminary knowledge of the theory of medicine as an introduction to the practical. After no small amount of labor and experimentation we reached the conclusion that recitation from text-books, conducted under the direction of a trained corps of competent instructors, afforded a better basis of theory than the didactic lecture. This arrangement had also another advantage of even greater merit, in that it freed the older and more experienced teacher, so that he could give his time to the practical or clinical demonstration of the theory. To do this properly, it was evident that he must have more time and opportunity than the so-called clinic of the amphitheater afforded. This could only be found in closer and more frequent contact between the student and patient than was possible at such clinics; hence, the plan finally adopted, namely, to break up the classes into small sections, and scatter such sections through the wards of hospitals and dispensaries, each under the guidance of a trained clinician, whose object would be less the display of his own learning than the eliciting of the student's knowledge, with a view to its correction and enlargement. Given then this broad basis of laboratory instruction, text-book drilling with clinical demonstration, superimposed and presented to such small sections as will insure the direct impress of teacher upon each student, we feel we have advanced a long way toward securing the best instruction that can possibly be presented to the medical undergraduate of to-day. To fully meet the demands of such a system, it is evident that patients are a necessity. The hospitals to which we have access, though many and large, by no means meet the requirements. This can only come from the control of a large outdoor or walking clinic.

For many years those of us who believed in this method of conducting medical education, dreamed of a college building which would be a large dispensary, surrounding and enveloping a medical school; a dispensary in which beside space for consultation with patients with every conceivable disorder, there should be close at hand space for the accommodation of students who could thus have ready access to every opportunity for demonstration. With room for each department to conduct its own clinical microscopy, one or more large lecture-halls for such lines of teaching as might still require didactics; museums filled with every required model or specimen needed for demonstration; work-rooms for every kind of teaching for which the cadaver may be required; space where all that pertains to physiology may be unfolded, and rooms for chemistry, to show not only what pertains to the inorganic of medicine, but all that is known or can be known upon the subject of animal or physiological chemistry.

This was our dream, and now when we awake and find this dream practically a reality—when we see rising before us all that our imagination so long pictured, and look back upon the years so vexatiously spent in making brick without the straw—we enter, as few have entered, into the feeling of the people of Israel as they turned their eyes to the land which Joshua and Caleb had told them of. And in a spirit of deep appreciation we begin here our part in the completion of the edifice which typifies the spirit and the body of our University.

With imposing presence it lifts itself upon its bed of rock, suggestive of some vast cathedral. We see its minarets, its spires and towers reaching heavenward, each marking the position of some component part or school, and telling in degree the sum of effort and perfection put forth and attained by each. Moving amidst its massive pillars and beneath its solemn arches, student and teacher alike approach its altar, and there find the visible presence of that sacred spirit of amity, unity, loyalty, and friendship which touches every soul that enters within its portals. Upon and within this stately edifice our place as yet is scarcely more than indicated. But filled with the spirit of that loyal faith given us in the example of our benefactor, imbued with the power of that high-souled aggression characterizing our University, and strong in the force of our own purpose, we engage to build for you as fair, as firm, as grand a spire as ever reared its head toward heaven. Faithful, aggressive, strong, we one and all pledge you our best and ever-increasing effort.

MEDICAL PROGRESS.

Epidemic Jaundice.—Pomeroy (*Boston Med. and Surg. Jour.*, August 4, 1898) gives an account of an epidemic of jaundice which existed in Calumet, Mich., and its vicinity from June, 1897, to January, 1898. In all there were about 695 cases of catarrhal cholangio-itis, in a population of about thirty thousand. No satisfactory etiology could be made out. To a certain degree the disease was regarded as a contagious, specific infection by the physicians in the vicinity, independent of temperature and drinking-water, and slightly, if at all, influenced by locality. The presence of several patients in a house seemed to concentrate the poison, so that invariably the last of the members of a family to fall sick had the severest symptoms. In no instance did every member of the family fall ill. Almost all of the patients were children from

three months of age and upward, only thirty adults being affected. In children the first thing for which a doctor was summoned was the discoloration of the skin; while in the adults the jaundice was preceded for several days by pain similar to that caused by the passage of gall-stones, though very much milder in degree. All of the patients attacked recovered and so there were no autopsies to establish the exact condition of the organs, and the most painstaking examinations of the blood, urine, feces, sputum, and gastric contents yielded only negative results. There was anorexia and a little vomiting occasionally, but gastro-intestinal symptoms were not generally present. There was a degree or two of fever for a brief period. The treatment employed was the giving of an anodyn, and a mercurial or saline purge. Afterward the phosphate of soda was given until the stools were of normal color and the bile salts had disappeared from the urine. For the itching the subcutaneous injection of $\frac{1}{20}$ to $\frac{1}{4}$ of a grain of the muriate of pilocarpin daily, gave the best results.

One curious feature of this epidemic of catarrhal cholangio-itis was the simultaneous occurrence of an unprecedentedly large number of cases of cholelithiasis. In one day the writer was called upon to treat four women in attacks of gall-stone colic, and the diagnosis was confirmed in three of these four cases by the passage of gall-stones in the stools.

Excision of Tubercular Cecum.—LEDIARD (*Lancet*, August 13, 1898) reports the case of a man, aged sixty-three years, upon whom he twice operated, once for an abscess to the right of the umbilicus, and once for the sinus which followed lancing of this abscess, and which discharged pus and occasionally fecal matter. When the sinus was exposed it was found to lead to the cavity of the cecum, and that organ was so badly riddled with tuberculosis that it was removed. The ascending colon was closed by suture, and the ileum was allowed to open externally as the condition of the patient did not warrant prolonging the operation sufficiently to unite these two portions of the bowel. The patient survived the operation two months, when he succumbed to pulmonary and cardiac trouble. This case is interesting from the fact that malignant disease of the cecum is usually cancerous rather than tuberculous.

Diabetic Coma Successfully Treated by Saline Infusion.—OLIVER (*Lancet*, August 13, 1898) was called upon to treat a man, aged thirty years, who had been suffering from diabetes for nine months. He was apparently improving when diabetic coma developed during a short railway journey. While still in a comatose condition two and one-half pints of saline solution was injected into the median basilic vein, and an active purge was given. Consciousness gradually returned and persisted until the time of report twenty-eight days later. For three days after the transfusion the patient passed a very small quantity of urine, about 21 ounces, instead of 140 to 200 ounces as he had been doing. After three days, however, the quantity rapidly increased until it reached 190 ounces daily. The advantages of even a temporary restoration of consciousness in persons, for example, who have business affairs to settle before death, is too plain to need amplification.

THERAPEUTIC NOTES.

The Production of Abortion by Nitrate of Silver.—PERLSEE (*Prague Med. Wochenschr.*, July 21, 1898) was called upon to bring about miscarriage in four cases of pregnancy complicated by nephritis and uncontrollable vomiting. He did this most successfully by the introduction of a stick of nitrate of silver above the inner os uteri. The stick should project about one-half inch from the holder so as to disinfect the cervical canal as it is introduced. Pains came on in from two to six hours after the cauterization. In every respect the delivery in the four cases was as perfect as could be wished for. The operation has the merit of simplicity, promptness, efficiency, and is aseptic.

Prolapse of the Omentum after Hysterectomy Cured by Posture.—FRANKEL (*Rev. de Thera.*, August 1, 1898) removed by the vaginal operation a myomatous uterus. The omentum appeared in the wound and was pushed up and held in place by an iodoform tampon. The following day there were some symptoms of intestinal obstruction and the tampon was therefore removed. It dragged out with it as far as the surface of the vulva the greater omentum. Not wishing to touch the omentum with any instrument at hand the operator put the patient in the knee-chest position and in a few minutes the omentum was restored to the abdominal cavity by the force of gravity. The patient made a good recovery. The success of this simple maneuver is worth remembering.

Suppurative Peritonitis Treated by Rectal Incision.—MOLIN (*Gaz. Heb. de Med. et de Chir.*, July 21, 1898) cites four cases of acute peritonitis with a collection of pus in the pelvis in which the abscess cavity was opened by a rectal incision. In every case relief was prompt and satisfactory. Three of the patients recovered without fistula. The fourth succumbed to an extension upward of his peritonitis. Rectal incision has been almost unanimously condemned by writers upon this subject. Delbet says that the drainage is very imperfect and often conducts fecal matter into the pelvis. Vauverts says that rectal incision is only a bad makeshift to which one ought not to resort unless the abscess is about to break into the rectum. These opinions scarcely accord with the results of spontaneous rupture into the rectum, for this termination is justly considered most happy, since it is almost invariably followed by recovery. Some authors state that fistulous tracts are apt to remain, inflaming the rectum and giving rise to new abscesses. The writer considers that these dangers are exaggerated and strongly advocates this method in suitable cases because of its simplicity and because it reduces to a minimum the shock of operation. This is a most important point, since many of these patients are extremely feeble.

SATURDAY, OCTOBER 15, 1898.

HOSPITAL REPORTS.

We had occasion a few weeks ago to refer to the scientific and didactic value of systematic reports of actual hospital work. The opinion then expressed as to the worth of such publications, is strengthened by the perusal of the medical and surgical reports of the Boston City Hospital. The present volume, the ninth in the series, is edited by Drs. Charles F. Folsom, W. T. Councilman, and Herbert L. Burrell, and is not only an excellent *résumé* of the work of the hospital during the past year, but is also of high literary and scientific worth.

Merely to illustrate the contents of the volume, a few articles will be singled out: "A Clinical Study of Eight Hundred Cases of Diphtheria," "Acute Degeneration of the Nervous System in Diphtheria," "Seventy-one Cases of Cerebro-spinal Meningitis," "The Local Anesthetics Used in the Eye," "Endocarditis from Gonorrhea," "A Report of a Case of Appendicitis, Showing the Relation of the Colon Bacillus and the Streptococcus Pyogenes as Etiological Factors." There are, also, reports from the Pathological Laboratory and clinical data of interesting cases. On the whole, the report shows the value of systematic endeavor in the study of patients in hospital services and what is thus gained by those under whose observation the patients have been, is shared by all who will read this record.

A signicant article is that of Dr. Burrell on "The New Surgical Services." Briefly outlined, it is a sketch of a scheme inaugurated by the trustees of the hospital for the employment of young men in the wards and for the retirement of the older surgeons to the rank of consultants. There are first, second, and third assistants, drawn from the hospital's dispensary, each of whom sees a certain amount of service in the operating-room and wards of the hospital under certain rules and restrictions. How well this redounds to the welfare of the surgical service is at once evident. Moreover, the younger men will acquire in the course of a few years, an immense experience, while they will not be obliged to wait until they are gray-headed before the privilege of operating in a hospital comes to them with its attendant responsibility. This project is new, but in every way commendable. We suggest the consideration of its features to the directors of some metropolitan hospitals, whose wards might be the gainers by the infusion of the blood of young men into their surgical services.

THE WORLD'S FOOD-SUPPLY.

IN latter years it has become the fashion for the President of the British Association for the Advancement of Science to make public in his Presidential Address some discovery of great scientific importance or to startle the thinking world with glimpses into the stores of the future. Sir William Crookes in his address before the Congress in Bristol a few weeks ago maintained the custom which his illustrious predecessors had established, by setting forth in great detail a stupendous mass of apparently incontrovertible statistics to show that all civilized nations stand in deadly peril of not having enough to eat, and this within thirty years. To all others than the rabid Socialist who hails the fulfilment of this prophesy as a solution of the destiny of the plutocrat, this information would be very depressing were it not that the illustrious forecaster points a way out of the collossal dilemma which has been unwittingly thrust upon us, and this by the utilization of the laboratory. Before we are in the grip of actual dearth, the

chemist will step in and postpone the day of famine to so distant a period that we, and our sons, and our grandsons may legitimately live without undue solicitude for the mortal future.

After full consideration of the wheat-growing lands of the world, Sir William points out that face to face with deficient acreage we must increase wheat-growing acre-capacity by the application of a "dominant" manure, which for wheat is nitrogen, fixed in the form of ammonia or nitric acid. The sources of available nitrogen are several: (1) From sulphate of ammonia which results from the distillation of coal in the process of gas-making, a comparatively inconsequential source. (2) From leguminous plants which bear on their roots nodosities abounding in bacteria endowed with the properties of fixing atmospheric nitrogen, also an insufficient source. (3) From the treasure of nitrogen locked up in the sewage and drainage of towns, an important source, but which at the present time is almost absolutely unutilized. (4) From nitrate of soda, or Chili saltpeter, which occurs in its native form over a narrow band of the plain of Tamarugal. This has been considered an inexhaustible source, but recent careful investigations would seem to point that this nitrogenous manure will be exhausted, at least in its present proportion of nitrate, in from twenty to thirty years.

The gleam of light amid the darkness of despondency lies in the conversion of nitrogen in its free state, which is one of the most abundant and prevailing bodies on the face of the earth, into nitrogen in a fixed state, which wheat demands. The fixation of atmospheric nitrogen, therefore, is, in brief, the solution of the problem which is so vital to the progress of civilized humanity. The agency, or force, which is to be the handmaid of this momentous transformation, is that which has already more than revolutionized the face of the scientific world, namely, electricity. A few years ago Sir William Crookes showed that nitrogen is a combustible gas, and the reason why, when once ignited, the flames do not spread through the atmosphere and deluge the world in a sea of nitric acid, is that its igniting point is higher than the temperature of its flame; not, therefore, hot enough to set fire to the adjacent mixture. But by passing a strong induction current the air takes fire and continues to burn with a powerful flame, producing nitrous and nitric acid. This source of nitrogen is inexhaustible, but the difficulty arises in generating electricity in the ordinary way, with steam engines and dynamos, that will convert it. To encompass this difficulty, the scientific utilitarian must harness Nature's inexhaustible sources of energy, the waterfalls of the world, such as has already been done with Niagara. It is estimated that by the utilization of the electricity now generated at Niagara, nitrate of soda would cost about $25 per ton, which compares very favorably with Chili nitrate at $37 per ton.

ECHOES AND NEWS.

Another Bellevue Hospital Appointment.—Among the new appointments made by Commissioner Keller to the Visiting Staff of Bellevue Hospital is that of Dr. Charles H. Chetwood as Visiting Surgeon.

Sickness in Porto Rico.—It is reported that 2500 soldiers are sick in Porto Rica, but in most cases their condition is not serious. Field hospitals are being erected as rapidly as possible, and the sick transferred to them with very favorable results.

Smallpox at Manila.—Reports from Manila, dated October 6th state that there had been fourteen cases of smallpox and six deaths from that disease among the American troops in the last two days. Eight deaths from typhoid fever have also been recorded.

Smallpox in Ohio.—It is now officially declared by the State Board of Health of Ohio that more than 200 cases of smallpox have occurred at Wapakoneta, and have been treated as chicken-pox. The disease is of a very mild type, and no deaths have occurred, to which is due the mistake in diagnosis. Rigid measures are being taken to eradicate it.

Harlem Medical Association.—At the meeting of the Association Monday evening, October 10th, the paper of the evening, "The Differential Diagnosis between Early Abortion and Ectopic Pregnancy," was presented by Dr. H. N. Vineberg. A Memorial of Dr. Philip Arthur Malleson, the former President of the Society, who died recently, was read by Dr. Wm. Westerfield.

Insanity on the Transport "Obdam."—The mishap to the transport "Obdam" from fire in her coal-bunkers necessitating her return to Santiago seems to have had a serious effect on the 240 convalescents on board. Three cases of insanity have already developed and it is feared that the disappointment caused by turning back may, owing to the weakened condition of the men, similarly affect others.

Improvement in Transportation.—The arrival of the transports "Panama" and "Missouri" from Ponce and other Porto-Rican ports, with 190 and 269 men, respectively,

shows a marked improvement in the transportation of the sick and wounded over those which conveyed the troops to Montauk. It demonstrates what can be done when sufficient care and effort are put forth. The condition of the ships was beyond reproach. Everything was neat and clean aboard them, and the men received proper care from the nurses and surgeons aboard.

American Academy of Railway Surgeons.—The following officers were elected for the ensuing year: President, Dr. W. W. Grant, Denver; first vice-president, Dr. J. F. Pritchard, Manitowoc, Wisconsin; second vice-president, Dr. J. P. Lord, Omaha, Nebraska; secretary, Dr. T. B. Lacy, Council Bluffs, Iowa; treasurer, Dr. C. B. Kibler, Corry, Pennsylvania; editor, Dr. Fred. J. Hodges, Ashland, Wisconsin. Place for holding the next meeting, Omaha, Nebraska, Obtober, 1899. Committee of Arrangements—Dr. J. P. Lord, Chairman; Drs. T. B. Lacey and Fred. J. Hodges.

Our Troops at Santiago. — The general health of the American troops is now better than ever before. The recent heavy rains have done much for the health of the camps. There has been a slight increase of ordinary fever, but all cases of yellow fever in the detention hospital are convalescent and practically ready to be discharged. The cooler weather is having an excellent effect on the sick. The troops stationed at San Luis have benefited greatly by a change of camps. General Ewers reports a reduction of sickness among his men from 700 to 30. The Second Immunes, at Altosongo, have only fifteen sick, with light attacks of malaria and dysentery.

Volunteer Surgical Talent for the Prince of Wales.—The Prince of Wales has been inundated with offers of assistance while he has been confined to his bed with a fracture of the patella. An equine bone-setter writing from a Park-Lane mews criticises the diagnosis of the surgeons in attendance. Three well-known peers urge his employment of some different persons "whose cures are marvelous," one recommending a Scotch gardener whose fingers are reputed to possess magnetic strength. An Irish Baronet is prepared to come immediately "to exert a something which has been in the family for years and cured my grandfather's game leg." A countess sent a bone which cured some family connection "by rubbing in a circular fashion over the weak spot," but the family treasure has been returned without a trial.

Yellow Fever in the South.—From the weekly report of the United States Marine Hospital Service, ending October 7th, it is apparent that yellow fever is steadily spreading in the States of Louisiana and Mississippi. Not only has there been an increase in the number of cases in the towns already infected, but new cases are steadily being discovered in neighboring towns and villages. The death-rate, however, continues very low, indicating the mild character of the disease. Unofficial accounts of a later date announce that nineteen counties in the State of Mississippi are infected and twenty-three cities and villages. Four interstate railroads have been obliged to suspend operations. The Mississippi State Board of Health has adopted the unwise course of advising all the citizens who can to leave the infected towns as the only method of escaping the fever.

Health of the Volunteer Camps.—Typhoid fever still continues its ravages at Camp Meade, Pa., several deaths from it having been reported during the past week. A number of cases have been sent to the Reading Hospital. The health of the New York troops is particularly bad, only 400 members of the 203d Regiment being reported fit for duty. More than half the men in the hospitals are homesick, but the surgeons say that after they have been home on thirty-days' furlough they will be all right. The food-supply according to Chief Quartermaster Howard has greatly improved. The rations are fresh and nutritious, and there is abundant supply. The men make no complaints about their food, but a large majority of them are anxious to go home. At Lexington, Ky., out of 584 cases in the general hospital there are 220 cases of typhoid fever. At Fort Thomas the non-typhoid cases are being transferred to the regular army hospital in order to lighten the hospital work sufficiently to allow the regimental surgeons and nurses to return to their regiments. At Camp Wikoff only 28 patients, all typhoid cases, remain in the general hospital. They will be transferred to New York and Brooklyn hospitals within a week. The railroad hospital for emergency cases, at Long Island City, was closed last week. The Red Cross Society has packed up its supplies and sent them to its headquarters in New York. The hospital corps and nurses, some 60 in number, will be retained until the government decides where to send them. The largest and most complete field-hospital in the world is to be erected at Montauk, L. I., about a mile from the site of the present general hospital. The buildings will be of brick and wood, and the plumbing and sewage will be complete. Work will be begun immediately.

The War Department's Reply to the Investigating Commission.—The Investigating Commission is not satisfied with the reply that Secretary Alger has made to its inquiries concerning neglect and incompetency in the management of the war. The answer has, therefore, been returned to the Secretary with a request for more detailed information. As an instance of the incompleteness of the replies, the question was asked, "Who had been influential in selecting the camp-sites?" The only answer given to this is that General Lee selected the camp at Jacksonville. No attempt seems to have been made to explain the causes of the hardships suffered by the soldiers at Tampa, before Santiago, or upon the transports. The Commission has busied itself the past week in considering reports of Adjutant-General Corbin, Surgeon-General Sternberg, and of the heads of other departments. Next week the Commission expects to make a tour of inspection of the various volunteer camps.

If Preventable, Why Not Prevented?—There can be little doubt that there is an intensified and gradually growing public interest in the campaign against "the white

plague," and it is gratifying to see that a portion of the secular press is lending its powerful support to the movement recently started by Sir Wm. Broadbent and a considerable number of the leading members of the medical profession in London, to take steps to check the continued prevalence of tuberculous disease in this country. The question is eminently one upon which an enlightened public opinion ought to be formed. The public mind must be aroused to the fact that consumption and other forms of tubercle are preventable diseases. "If preventable, why not prevented?" as the Prince of Wales said on a memorable occasion. A public meeting will be held early in October. At this meeting the formation of an association for the prevention of tuberculosis on lines similar to those of the associations which are doing such good work in France and Belgium will be proposed, and other means will be concerted for placing sufferers from pulmonary consumption in its early stages under the most favorable conditions for recovery.—*British Medical Journal.*

The Navy's Loss in the War.—The total loss in the navy in killed and wounded in all the engagements of the Spanish War is eighty-four men, of whom seventeen were killed and sixty-seven wounded. In the naval engagement at Manila one man was killed and nine wounded, all of the latter returning promptly to duty. In the battle with Cervera's fleet at Santiago July 3d, one man was killed and ten wounded, all the wounded returning to duty. In the attack on the Santiago forts June 22d, one man was killed and eleven wounded, seven of whom returned to duty. The heaviest loss of the navy was at Guantanamo. There were twenty-two casualties in that 100-hour fight, six were killed, and of the sixteen wounded men nine returned to duty, three were invalided from the service, and four continue under treatment. At Cienfuegos one was killed, one died from wounds, and ten were wounded, nine of whom returned to duty. At Cadenas the torpedo-boat "Winslow" and the gunboat "Hudson" lost five men killed and three wounded, all the latter returning to duty. In the bombardment of San Juan one man was killed and seven wounded, six of whom returned to duty. There were four other casualties in as many separate engagements. Considering results obtained, this list is said to be the most remarkable in the naval history of the world.

The Navy's Medical Corps.—The annual report of the Surgeon-General of the Navy, W. K. Van Reypen, has been submitted for publication. The medical department, like all the other departments of the Navy, displayed rare good judgment and foresight in preparing in advance for every emergency. When the "Maine" was destroyed preparations were begun immediately for every contingency. The hospitals were fully occupied, plans were prepared for pavillion wards, and the naval laboratory was put in a condition of efficiency to furnish medical and surgical supplies in any quantity. When war seemed imminent every vessel likely to be engaged was given a full outfit of medical supplies for war. In anticipation of a large increase of the navy proper outfits were prepared and boxed ready for call. The result was that there was not an instance during the war of any vessel being obliged to wait for her medical stores. It was known that the medical corps was inadequate in number for war, yet there was no law authorizing the employment of volunteer medical officers. Medical boards were sent out, however, in anticipation, to the principal cities to examine applicants for appointment. Consequently when war broke out the medical department had at hand from which to make selections of volunteer surgeons, a long list of well-educated men, and thirty-seven of these were appointed out of 2000 applicants. Surgeon-General Van Reypen says: "They have rendered efficient service, and have been a credit to the Navy. Some have had unusual and trying experiences, but they have accommodated themselves to their environments, and have justified their appointment." Only one medical officer was killed during the war, Assistant-Surgeon John Blair Gibbs, who fell at Guantanamo, serving with the Marine Battalion. The valuable services rendered by the hospital ship "Solace" is briefly set forth. Praise and credit are bestowed in this report upon the patriotic women who ably supplemented the efforts of the Government in contributing supplies for the sick and wounded. Most favorable mention is also made of the female nurses who volunteered their services and were assigned to duty in hospitals. The report concludes as follows: "I cannot close this portion of the Bureau's report without bearing testimony to the efficiency, skill, and devotion to duty of the personnel of the Medical Department. Not a word but of praise has the bureau heard of any of them—regulars or volunteers. When war was imminent they vied with one another in their efforts to get on fighting ships. Some had greater opportunities than others, but all have done well the work assigned to them. The medical officers of the vessels in the fight at Manilla and in the battle of the 3d of July shared the dangers of their comrades, and should participate in the praise accorded them. The medical officers of the 'Solace' have the honor of inaugurating the first complete system of antiseptic surgery at sea. They have adapted means to ends, have improvised apparatus, have been fertile in expedients, and have the satisfaction of having demonstrated that with skill and intelligence the percentage of mortality among the patients on a well-equipped ambulance-ship will be no greater than in the hospitals on shore. Medical Inspector Persons found himself suddenly confronted with 226 Spanish sick or wounded prisoners in a hastily established hospital. He was equal to the emergency, and he and his assistants were complimented by Admiral Cevera when he visited the camp. The medical officers of the other hospitals have had sudden large accessions of patients. They were always ready and always cared for them well."

For Chronic Sciatica the following stimulating liniment is recommended:

CORRESPONDENCE.

COLORADO A NATIONAL HEALTH-RESORT.

[Extracts from a private letter to the Editor.]

DEAR DR. GOFFE:—It is a long time since you have heard from your consumptive friend out West, but that does not mean, I assure you, that you have been out of my mind. I am, indeed, very happy and thankful. I have now reached a weight that was never anticipated, 150 pounds! How's that for Colorado? I never felt so well as I do now; never knew before what it was to be a good animal, and that, in spite of the fact that I have had two slight hemorrhages this summer. At the time these occurred I was rather pleased than otherwise, for here, you know, experience has shown that if one must be a consumptive its much better to be classed as a hemorrhagic case. Though this town is the Mecca of so many hopes there is indeed an awful amount of sadness here. Many come to find in this grand climate restored health, and in consequence happiness, but there is an army of sufferers whose disease, being advanced, are beyond hope, and, though many such live longer here than elsewhere, still the fatal ending is none the less sure.

That this latter class should come here is of course all right when they are possessed of the necessary funds; but in the cases of so many "funds" means just enough money to get here, and, as privation is absolutely incompatible with the cure of consumption, getting here means to die far away from home and from one's friends and relatives. It's a great shame, indeed, that physicians persist in sending such cases here.

As there seems to be no end of money in the East for the building of unnecessary institutions, would it not be a glorious thing if some one would build here a great sanatorium, such as are found in Germany, where poor people with phthisis might be sent, some to find renewed health and usefulness, and others to go down gradually, easily, living longer than they could anywhere else? In view of the statistics which such an institution would furnish, there would be no place for the mountains of New York or for other Eastern sanatoria, and little for Southern California.

You may think that I am over enthusiastic with regard to the climate of the lower Rockies—the slope of the Sangre de Cristo, as the Spanish settlers called them—and this in view of my own recovery, but, I assure you, that could you personally interview the many "third stagers" that I have, people who have come here only after wasting that golden period, the first stage, in the health-resorts of the East, you would feel as I do. Doubtless many consumptives recover elsewhere (given the proper environment and not too degenerate a tissue, tuberculosis shows a natural tendency to cure), but it is my firm conviction that where one gets well in the East a hundred would recover here.

Just think a bit; on the slopes of the Rockies may be found all grades of humidity (except wetness), all grades of temperature and all grades of altitudes. What a natural sanatorium! The most suitable climate may be found for any given case and all within a radius of 1000 miles. The expense attendant upon comfortable living is the one great obstacle—which time, meaning practically increased population, and irrigation will remedy.

I honestly believe that most Eastern physicians are profoundly ignorant as to the health-resources of this great Western country. A department of climatology is a needed addition to most medical colleges. I know from my own experience that I had great difficulty in finding any one to tell me where to go. Why! As you know my physician in New York wanted to treat me by hydrotherapy. Think of it! Keep a man with consumption in that death-dealing climate when there is a Colorado—and treat him with cold water! With a humidity of from 60° to saturation I cannot understand why additional hydrotherapy is required in New York. Here I read, drive, smoke, sleep, and drink whisky and milk, and therein lies the cure of tuberculosis—with the possible exception of the smoking. I have been called into consultation quite a number of times (hanging around clinics in New York has some virtues after all), have operated successfully upon a floating kidney and an appendix, and the Lord willin' intend to hang out my shingle October 1st.

Sincerely yours,

——, M.D.

COLORADO SPRINGS, COLORADO, September 24, 1898.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

OPENING EXERCISES OF JEFFERSON MEDICAL COLLEGE AND OF THE MEDICO-CHIRURGICAL—MORE HOSPITAL TRAINS—HOSPITAL BEQUESTS—PERSONAL NOTES—PUERPERAL INFECTION—A CASE OF OSTEITIS AND A CASE OF INTESTINAL OBSTRUCTION.

PHILADELPHIA, October 12, 1898.

PRESIDENT WILLIAM POTTER inaugurated the seventy-fifth annual session of Jefferson Medical College last Monday evening, October 3d, in the hospital building. In a few brief remarks he commented on the power of young men, particularly evinced by the number barely out of their teens who were engaged in the war, and on the energy displayed by them in all branches of the service, a fact noted by him on his trip to Porto Rico on board the yacht "May."

Dr. Edward P. Davis followed with an address in which he urged students to learn "by educating the eye, the ear, and the hand, so as to study patients by reasoning and not by dead memory." He believes that among the lessons learned from the war is the necessity for medical men to enforce respect for their opinions, so that they cannot be disparaged by incompetent officials. In conclusion he said: "Men can well be proud of belonging to a nation which in 100 days put forward the dial of liberty 100 years, and it is well to be an American citizen."

The Medico-Chirurgical exercises were presided over by Dr. John V. Shoemaker, who spoke of the high percentage received by graduates of the school in competitive examinations, and of the increased facilities for

study. Dr. Seneca Egbert welcomed the students, spoke of an increased attendance and gave some practical hints as to the best methods of studying.

The 500 sick soldiers who were expected to arrive on hospital ships this week were finally sent to other ports, but as if to make up for this deficiency, three hospital trains were sent to Camp Meade bringing back nearly 200 men, most of whom had typhoid fever.

On Monday 49 men were brought by the Jefferson Hospital train which consisted of six cars, each arranged as a ward with its physician, head nurse, two assistant nurses and an orderly. The train was under the direction of Dr. Joseph S. Neff and Dr. H. A. Hare, having as assistants Drs. Loux, Salinger, Williams, and Wiggins, with a large corps of nurses, one of whom, chief dietician of the hospital, prepared all food and nourishment on the train.

The other trains were sent by the German Hospital, which brought back 60 men in charge of Dr. Carl Frese, and the Pennsylvania Hospital, which brought 72 men in charge of Dr. Robert Le Conte.

The following bequests are made in the will of Henry Pfander, which was admitted to probate last week: Jewish Hospital Association of Philadelphia, $2000; Jewish Maternity Association of Philadelphia, $1000; Jewish Foster Home and Orphan Asylum of Philadelphia, $2000.

By the will of Colonel Joseph M. Bennett a large amount of property is bequeathed to various institutions in this city, the University receiving nearly $500,000, which, it is directed, is to be used to further the co-education of men and women. Unfortunately, Colonel Bennett's daughter is to contest the will on the ground of undue influence and mental incapacity, and the estate may thus be tied up in litigation for some time.

Dr. George E. de Schweinitz has returned from the Adirondacks, where he spent September, Dr. J. William White, from a bicycling tour of Europe, and Dr. Joseph M. Leidy, from Narragansett. Dr. J. P. Bolton is acting Demonstrator of Chemistry at Jefferson, Dr. Jacob having left the city as a contract surgeon in the army.

Dame Rumor connected the name of Dr. Guiteras with the project of establishing a medical school in Cuba, but he has denied having any idea of severing his connection with the University.

Samuel Dickson, Joseph Harris, S. Weir Mitchell, M. D., Horace H. Furness, and J. G. Rosengarten have been appointed by the Trustees of the University of Pennsylvania a committee to arrange for a memorial meeting to Dr. Pepper. The American Philosophical Society, of which Dr. Pepper was vice-president, has taken similar steps.

"The Prevalence and Prevention of Puerperal Infection in Private Practice" was the title of a paper read by Dr. Shoemaker at the County Medical Society, September 28th. He thinks private practice has failed to keep abreast of institutions in lessening the mortality and described ideal obstetric conditions which can be partially obtained by the use of such simple means as a small scrubbing-brush, bichlorid solution, napkins which can be baked in an oven, and a cheap cotton suit to be worn by the physician. In the discussion Dr. R. C. Norris advocated the use of rubber gloves in septic cases.

Dr. Anna M. Fullerton spoke of the far-reaching effects of gonococci in a paper on "Gonorrhea of the Uterus and Its Appendages."

Dr. W. J. Taylor reported a case of "Intestinal Obstruction by a Band of Omentum," which occurred in a woman aged forty. Celiotomy was performed, a band encircling the intestine and passing through the mesentery was severed, and after the intestine had been opened and emptied of fecal matter, the wound was closed. Two years later obstruction occurred again, the intestine being caught under a band of adhesion.

"A Case of Osteitis Resulting in Circumscribed Suppuration or Abscess of the Lower End of the Tibia" was reported by Dr. J. Ewing Mears. This followed an injury and was variously treated until a skiagraph revealed the true trouble. An incision was made, a groove cut with the chisel, and later the curette was used, the patient making a good recovery. In the discussion Dr. Roberts suggested that relief was obtained by cutting through the periosteum and thus relieving tension. Dr. Barton, on the other hand, believes that the trouble in these cases is more deeply situated and most likely due to osteomyelitis.

MEDICAL MATTERS IN CINCINNATI.

[From a Special Correspondent.]

CINCINNATI, October 11, 1898.

THE Cincinnati Academy of Medicine held its first session of the season, September 26th, Dr. Louis Schwab in the chair. This being the regular evening for case reports and the presentation of specimens, Dr. B. F. Lyle reported a case of tubercular pericarditis and carcinoma of the stomach. Patient colored, aged forty-four; entered the hospital with symptoms of cough and expectoration, weakness, loss of appetite and dyspnea. A physical examination showed dulness in both apices anteriorly and posteriorly, and over the entire lower lobe on right side posteriorly, with bronchial breathing and sibilant râles over these areas. Temperature, 100° F.; pulse, 104; respiration, 36. The patient had lost forty-five pounds in weight, and progressively grew worse. Post-mortem [specimen presented] showed the pleuræ adherent to pericardial sac but slightly to costal pleura; pleural cavity on each side contained one pint of clear fluid. The pericardial sac was obliterated by a tubercular pericarditis, the tubercular tissue or infiltration being one-half an inch thick over the left ventricle and one-fourth of an inch thick over the right ventricle. Anterior and posterior mediastinum filled by tubercular glands. Lungs were infiltrated by a few small tubercles, the dulness being due to the mediastinal glands and infiltrated pericardium. There was a large fungus carcinoma in the pyloric end of the stomach. The omentum was rolled up and tubercular, and tubercles were present in other parts of the peritoneum. Dr. Lyle called especial attention to the meager symptoms, the confusing physical signs, the rarity of such

a specimen, and the absence of any symptoms that would lead to the diagnosis of such an advanced carcinoma of the stomach.

Dr. Magnus Tate reported a case of double pyosalpinx in which adhesions to the intestine were excessive. The main interest in the case attached to an accident during convalescence. Three days after operation the patient fell out of bed, suffered severe pain in the abdomen, and died in a few hours from peritonitis and shock. Dr. Tate stated that he had separated the intestine from the tumors very gently and felt certain that he left no opening into the bowel at the time of operation. Dr. C. A. L. Reed explained the accident by showing how, in these cases, the peritoneal coat may often be removed and the muscularis as well, leaving the mucosa intact. A slight force such as falling out of bed might easily cause a rupture in such a case.

Dr. Edwin Rickets presented an enterolith removed from the abscess cavity in a case of perforative appendicitis, which was peculiar in the fact that the pain began as a simple colic, and rapidly presented symptoms of intestinal obstruction with extreme distention of the intestine. The patient died of general peritonitis, even though an operation had promptly relieved the intestine of gas by puncture and the local condition in and around the appendix. Dr. Twitchell believes that it is always meddlesome surgery to operate in any case of appendicitis in the acme of the attack and that more patients die when operated upon at this time than if no operation is performed. He believes that most cases of colic are mild attacks of appendicitis dependent upon edema and increased peristalsis in the head of the colon and appendix and that the old practitioner's idea of a hypodermic of morphin to relieve the peristalsis and a saline purge to relieve the edema is the proper one for all cases of mild appendicitis. The only cases in which operation is justified are the recurrent ones, which are to be operated on in the interval, and the late cases which have formed a circumscribed abscess.

Dr. Reed raised serious objections to such a view of appendicitis and expressed a conviction that such principles would kill many patients if carried into the practice of surgery.

Dr. Ricketts also presented a gall-stone weighing 388 grains which he had removed from a patient who had suffered from one attack of pain in the region of the gall-bladder many years ago with no further disturbance in this region until the attack of repeated chills, fever, and sweat for which the patient was operated upon. The gall-bladder was full of pus and the patient died from sepsis. Attention was called to the absence of jaundice and biliary colic and the dictum formulated that all cases of biliary colic should be submitted to operative treatment.

Dr. Gustav Zinke also reported a case of empyema of the gall-bladder. His patient had suffered from biliary colic but at the time of operation was almost moribund from a septic condition of the gall-bladder. Operation resulted in the removal of a very large number of small gall-stones, the liberation of much pus and the recovery of the patient. Dr. Zinke stated that this was the first patient he had ever found it necessary to subject to operative treatment, having succeeded in relieving all others by the use of salicylic acid, bicarbonate of soda, and Carlsbad salts. He attributed his success by internal medication to a fortunate series of cases, yet believes that it does argue against Dr. Ricketts' principle of operating in every case of biliary colic.

Dr. M. L. Heidingsfeld reported a case of abscess of the prostate gland which ruptured primarily into the rectum, later into the urethra, and terminated in recovery.

Dr. S. E. Allen reported a case of middle-ear disease in which pain was intense and persistent yet there was no tenderness over the mastoid. A mastoid operation was performed after two weeks with no findings, but with absolute relief from the pain. The patient's temperature continued high, however, and in a few days metastatic abscesses presented in the left thigh, left arm, and right foot. These were opened, and after a long precarious illness the patient recovered.

The appointment of Dr. P. S. Conner as a member of the "Commission to Inquire into the Conduct of the War" appeals to the profession of Cincinnati as a most fitting choice. Dr. Conner is a man who experienced a very unusual service in the Civil War as a surgeon and as a director of hospitals. He is, therefore, entirely familiar with the exigencies of actual service and understands fully the difficulties and possibilities of the field hospital. His constant engagement in hospital work, since the war, at the Cincinnati and Good Samaritan Hospitals, increases the value of his opinion on matters of medical requirements and hospital management. Furthermore, he is a broad man of firm and fearless convictions, and complaints based upon sentiment alone will have no weight in his conclusions. The administration and the American people may feel a deep satisfaction in the appointment of a man whose integrity is unimpeachable.

The medical colleges open this week with the usual events of matriculation and introductory lectures. At the Medical College of Ohio a few changes are noted in the faculty and lecturers. Dr. Samuel Nickels, professor of materia medica and therapeutics, has resigned from active duty and has been made emeritus professor in this branch. Dr. B. Knox Rachford has been chosen by the faculty to fill his place, and Dr. Allyn C. Poole will be transferred from the chair of chemistry to fill that of Dr. Rachford, as professor of physiology. Dr. Stephen C. Ayres has been elected to fill the chair of professor of ophthalmology and otology. Dr. William H. Crane has been made lecturer on chemistry to fill the vacancy left by Dr. Poole. In the absence of Dr. Wolfstein, Dr. Horace J. Whitacre will lecture on pathology and will also conduct the laboratories in pathology.

The vital-statistics report of the board of health for August shows the total number of deaths to be 375, which is the lowest August mortality during five years. Mortality-rate per thousand 11.11. Among the infectious and contagious diseases reported there were: measles 13, diphtheria 16, scarlet fever 7, typhoid fever 26, phthisis 33, pertussis 14.

Berlin.

NATURE AND CAUSES OF PERNICIOUS ANEMIA—COMPLETE FATTY METAMORPHOSIS OF A KIDNEY WHICH HAD CONTAINED A STONE FOR MANY YEARS—MYOSITIS PROGRESSIVA OSSIFICANS.

GRAWITZ discussed the difficult subject of anemia not due to external injury nor to disease of any organ at a meeting of the Huffeland Society, May 12th. The clinical picture of pernicious anemia is well known. At autopsy there is generally present a secondary degeneration of the cardiac and renal tissues, as well as of the glands of the stomach and intestine. In the majority of cases there is also a red, so-called lymphoid condition of the marrow of the long bones. The changes in the blood have been frequently described. The red cells become fewer and fewer, until they may number not more than half a million to the c.mm. Macro- and microcytes appear, and especially poikilocytes in great numbers, and nucleated red cells called megaloblasts. These changes of the blood are not confined to pernicious anemia, however, so they do not alone suffice for diagnosis, as do the changes in the blood in leukemia, for instance.

The physical conditions of the blood are not less important than its histological characteristics. If a quantity of it is drawn in a glass and allowed to coagulate the number of red blood-cells is visibly greatly diminished, while the proportion of serum is correspondingly increased. Sometimes as much as ninety per cent. of the contents of the glass after coagulation will be serum. This serum is essentially normal, so that the conclusion may be safely drawn that the disease is one of the cells and not of the fluids of the blood. In certain wasting diseases, on the other hand, such as tuberculosis or some gastric or intestinal affections, there is an atrophy of the blood, similar to that of the muscles, and under such circumstances there is a lack of albumin in the plasma as well as a diminution in the number of corpuscles. The fact that the cells of the blood retain their character in these diseases is probably because the disease exerts no especial influence upon the blood-making organs. These organs suffer from the general anemia, and as this progresses they fail more and more in the required quantity of the blood. In other wasting diseases the blood-producing organs are directly injured, and according to the intensity of this influence the constituents of the blood are altered in character. Such are repeated hemorrhages, anemia after severe infection, chronic suppuration, malaria, osteomyelitis, carcinoma, sarcoma, chronic diseases of the liver or kidney, etc. In marked instances of these diseases the histological examination of the blood may give the same results as in the case of pernicious anemia, but the plasma is very deficient in albumin, and not as that in pernicious anemia, essentially normal. The proof, therefore, is positive that in pernicious anemia there is a morbid alteration of the cells of the blood, and not simply a general marasmic condition. Unfortunately, however, this distinction is not marked with sufficient clearness in all cases to permit one to say from the blood examination alone whether a given case is one of pernicious or of secondary anemia. Far more valuable for differential diagnosis is the course of the disease. In secondary anemia the blood regains its normal character if the cause of the anemia can be removed, as after clearing the intestine of ankylostomata, or the extirpation of a pyloric cancer.

Although the etiology of pernicious anemia is still obscure, the following conditions have been considered to be of significance by different observers:

Long-continued disturbances of digestion leading to chronic catarrh of the stomach and intestine, and constipation.

Pregnancy was once considered an important etiological factor, but this view is not now so strongly adhered to. By pressing on the intestines, however, a pregnant uterus may increase digestive disturbances.

Repeated small hemorrhages in persons whose constitutions are not strong lead sooner or later to a condition in which the blood-building organs are unable to make good the losses, and the red cells reproduced are imperfect in quality and of insufficient quantity. Therefore the marasmic conditions grow constantly worse. In the light of the best evidence at present attainable this is the correct explanation for most of the cases of pernicious anemia.

Constitutional syphilis is also an important causative factor, not on account of the action of any virus, but because of the cicatricial changes produced by it in various organs, especially in the marrow of the bones.

Conditions affecting the general health, such as poor food, bad air, too frequent pregnancies, shock, and other nervous disturbances may also help the individual into a condition of pernicious anemia.

Chronic poisoning, especially with repeated small amounts of carbon monoxid, should also be mentioned.

There are, too, cases of anemia caused by the bothriocephalus and by the ankylostoma which do not disappear with the removal of these parasites.

One ought to be on his guard against the careless habit of calling all fatal cases of anemia "pernicious," and all cases which recover "simple" anemia.

At the Medical Society, July 20th, ZONDEK showed a preparation of a kidney which, owing to the presence of a stone for eleven years, had undergone complete fatty metamorphosis. The organ was, when removed, about twice the natural size, and nowhere was any parenchyma to be observed. The ureter was much enlarged and thickened, and the pelvis contained two stones. The symptoms at the time they were first noticed, eleven years before the nephrectomy was performed, were those of a stone in the kidney, with intense pain and fever, compelling the patient to remain about eight weeks in bed. Then for years there was very little trouble, but more recently the pains in the loin recurred with such severity as to lead to the operation indicated.

JACOBY showed a man, aged twenty years, who suffered for eight years with pains in his neck of a rheumatoid character, and which were followed by the calcification of these muscles. These had been in this condition

for four years. Later bony areas appeared in the masseters and in the muscles of the back. The clinical diagnosis was confirmed by the Röntgen-rays. The parts affected were almost immovable.

Virchow showed a patient, also a man, who had been suffering for years from a progressing myositis ossificans, until a large part of the muscles of the back and a part of those of the limbs were involved. In portions of the body where there are no muscles, the deposit of lime-salts also occurred. Thus an exostosis had formed on the side of the great toe, and had grown until it looked almost like a sixth toe, although it was not attached to the bones.

SELECTION.

NOTES ON OPHTHALMOLOGY IN VIENNA.[1]

By REGINALD E. BICKERTON, M.B., Ch.B.(Vict.).

The following remarks apply more particularly to the operative methods and procedures followed in Professor Fuchs' Clinical Department in Vienna, and are all written from personal observation, in most cases as one of the assistants.

ASEPSIS AND ANTISEPSIS.

Sterilization of Hands and Dressings.—All hand towels, cotton-wool for sponging, dry and wet, for dressings and pads, are first sterilized in a hot-air sterilizer for at least one hour, usually two. During the process the cotton-wool for sponging is contained in cardboard cases: the cotton-wool pads used for dressings immediately after operations, in porous porcelain jars; the towels and gauze used for dry sponging being put in round metal cases with perforated tops and bottoms. After sterilizing, these dressings are never touched by hand again till the operator places the dressing in position after the operation. The cotton-wool which is used for wet sponging is put into corrosive-sublimate lotion (1–5000) by means of a pair of sterilized forceps. After washing their hands and sterilizing, more or less, with corrosive-sublimate lotion 1–1000, the operator and his assistant dry their hands on a sterilized towel, which is then laid across the patient's chest close up to the chin, so that, if any instrument are laid upon it, they do not necessarily become infected.

Irrigation Lotions. — Corrosive-sublimate lotions of two strengths (1–2500 and 1–1000) are used. Carbolic-acid lotion (1–40) is used only for laying instruments in and for boiling and keeping silk ligatures in. Saline solution 1–1000 is used for irrigating conjunctival sacs before operation. Separate irrigation nozzles are kept for purulent cases and for trachoma cases. Boracic acid (1–500) was used in one case for syringing out the anterior chamber, the wound having become purulent after an operation.

PREPARATION OF PATIENT.

Treatment Previous to Operation.—All cataract cases are kept in the hospital for a day before the operation is undertaken. In many unclean-looking cases the eye to be operated on is syringed out with corrosive sublimate (1–2500) the night before the operation and a pad applied. The syringing is repeated on the morning of the operation, and a simple rubber pad is put on without any further dressing.

Immediate Preparation for Operation.—When the patient is on the operating-table, immediately before the operation is commenced, the eye is again thoroughly well sponged and irrigated, either by the operator himself or his assistant. If the case happens to be a particularly unclean-looking one, the eyebrows, lids—especially the ciliary margins—and surrounding skin are well washed with a neutral soap and sponged with corrosive sublimate, then dried. In all cases the upper lid is everted and the palpebral conjunctiva well sponged with cotton-wool dipped in sublimate—1–1000 first, then 1–2500—particular care being taken to cleanse thoroughly the fornix conjunctivæ. The lower lid is then cleansed in a similar manner, the lacrimal sac being always pressed upon to make certain that there is no retained secretion or abnormal secretion which might regurgitate under the slight pressure of the pad after the operation. The lids are then allowed to fall back into their normal position. Irrigation of both conjuntival sacs is next performed by means of a flattened irrigation nozzle, the fluid used being contained in glass bottles placed some ten feet from the floor. Saline solution is usually employed, the nozzle being placed well up into the fornix. A thin layer of sterilized gause dipped in sublimate lotion is now placed over the patient's face, eyebrow, and nose, a hole being made previously in it for the eye. These preparations apply to all operations.

INSTRUMENTS.

For Aseptic Cases.—All instruments, except those reserved specially for purulent conditions and trachoma, are kept in a glass instrument-cabinet with glass shelves and metal racks for holding them. Knives and all cutting instruments are kept in the same way, and not in separate cases, and they do not seem to become rusted from exposure.

For Septic Cases.—All instruments used for abscesses, Saemisch's operation, and purulent conditions generally, are kept in a separate wooden box, being well boiled both before and after every operation. Instruments used for trachoma cases of any kind, whether for lid operations or for bulb operations, also Knapp's roller forceps, are kept in a separate wooden case, and not in the general instrument cabinet.

Preparation of Instruments.—The instruments about to be used for any operation are placed in a small metal rack with their points and part of the handles projecting; the whole rack with instruments thereon is then placed in a tin sterilizer containing two liters of boiling water with five grams of sodium carbonate dissolved in it to prevent rusting. They are boiled in this for two minutes, or never less than one minute. A separate sterilizer is kept for abscess and trachoma instruments, similar to that used for non-infective operations. Immediately before use the rack with instruments on it is taken out of the

[1] Reprinted from the *British Medical Journal*, September 17, 1898.

sterilizer by means of a wire carrier, and the whole thing placed on a sterilized porcelain plate and covered with a double layer of sterilized gauze dipped in corrosive-sublimate lotion. The operator and his assistant are the only persons then who touch the instruments, which are used usually while still warm. If any unusual number of instruments are required they are first sterilized by boiling, then placed in carbolic-acid lotion (1–40), and used wet. All the knives used, and most of the other "handled" instruments have bone handles, and the boiling for this length of time seemed to have very little effect in loosening the handles. The handles of the instruments used for abscesses always became loose sooner than any others, as these instruments were boiled for a longer time both before and after each operation, sometimes for half an hour after the operation.

SUTURES AND NEEDLES.

Sutures.—Catgut is used for all conjunctival sutures, and various thicknesses of silk for plastic operations, adjustments, Snellen's sutures. Catgut sutures are kept in a spirituous corrosive-sublimate solution, and are not boiled or put into any watery solution before use, but simply laid between the folds of sublimate gauze. The silk used is first wound on to a big reel, and the reel and silk then boiled for an hour and a half in carbolic lotion (1–40.) It is then removed from the big reel on to smaller glass reels, on which it is kept and from which it is cut off as required. These smaller glass reels are then boiled for another hour in 1–40 carbolic, and are afterward transferred to glass dishes, in which they are kept in 1–40 carbolic. These repeated boilings have very little effect in making the silk lose strength.

Needles.—The needles used have patent and split eyes, which facilitate threading. The needles about to be used are first boiled, then the silk threaded, and the needle, together with the silk again dipped in boiling water for half a minute. They prove absolutely aseptic, and suppuration never took place round a suture.

COCAIN AND ANESTHETIC SOLUTIONS.

A three-per-cent. solution of cocain is used for all operations where cocain in required. A separate bottle and drop tube are kept for all trachoma cases, the bottle being labeled "trachoma" and colored. Another bottle labeled "abscess cocain" is kept for all abscess and purulent cases. Thus the risk of carrying infection by contact of the drop tube or bottle from infective cases to non-infective cases is eliminated. All the cocain used is in sterilized solution, and all cocain used during an operation, after an incision has been made into the eyeball, is, to commence with, a sterilized solution put in sterile drop bottles, which are then put in a glass beaker uncovered; the beaker is then placed in the hot-air sterilizer for an hour, then taken out and a solution of acid thymol, 3–1000, poured over the bottles till they are completely submerged; they are kept in this, and no one touches them without first sterilizing his hands. Atropin and eserin are kept in the same way, being in drop bottles with "turn-off" stoppers. Cocain is instilled a quarter of an hour before any operation, and no fewer than four times during this time.

Hypodermic Solutions.—The solution of cocain used for hypodermic injections is of the strength of three per cent. The syringes and needles are kept in glycerin, and filled with glycerin when not in use; this prevents rusting, and also the entrance of extraneous matter into the barrel of the syringe. Cocain injections are employed in extirpation of the lacrimal sac and gland, in operations for trichiasis, entropion and ectropion, Panas' and Spencer Watson's and Von Arlt's operations for advancement of muscles, for meibomian cysts, styes, Knapp's roller forceps operation for trachoma, and in all small plastic lid operations. The quantity injected is 15 and 20 and 30 c.mm., and in the ten months during which I witnessed several operations performed every day I never saw any ill after-effects from its use. A solution of cocain with morphin is also occasionally used. Separate hypodermic needles are kept for trachoma cases. Before use the needles are in all cases held in boiling water for half a minute. General anesthetics, pure chloroform, pure ether, and A. C. E. mixture are employed. Skinners' mask is used in every case.

THE OPERATIONS.

Position of the Operator.—The operator stands in front of the patient, rarely behind. Right eyes are operated on by the left hand, and vice versa.

Light.—Operations are performed by daylight in most cases. When the light is very bright it is admitted from above the level of the operator's head only, so that the light comes from above and not directly from the side; by this means much of the corneal reflection is done away with. A small hand electric lamp is usually used for discissions, and when the daylight is insufficient.

Speculum.—This instrument is not usually used in cataract extractions or iridectomies unless the patient is very refractory. The lids are held apart by the assistant, and allowed to close immediately the primary incision is completed, and also between each step of the operation. The speculum generally in use has an automatic spring, without adjusting screw, and tends to separate the lids always wider and wider apart, in this way causing undue pressure on the eyeball. Desmarre's lid elevators are used in enucleation and exenteration of the orbit.

Cataract Extraction.—The complete operation is always done at one time. A large conjunctival flap is made. The operation with iridectomy is performed slightly more often than the operation without; for example, out of 400 extractions 206 were performed with iridectomy. The number of cases in which prolapse of the iris occurred was very small. Graefe's knife was always used. The lens capsule was opened by means of capsule forceps having teeth on the under side of bent arms. The lens entire, in its thickened capsule, was occasionally removed in this manner. If the forceps failed to open the capsule the cystotome was used. The lens was expressed by pressure applied by means of the finger through the lower lid, the edge of the lid being used in much the same manner as a cataract spoon. The iris almost invariably re

quired reposition after the lens had been removed, when the operation had been done without iridectomy. One or two drops of eserine solution (one per cent.) sterilized were instilled after reposition of the iris and of the conjunctival flap. This was done only in operations without iridectomy. Both eyes were covered by soft dry wool pads; no head bandage was used, but a Snellen's aluminum shield was placed over the operated eye. If any difficulty was experienced in removing the lens, or of the vitreous presenting before it was removed, a small pair of forceps with curved arms terminating in each in a small hook was used as a vectis; the forceps were passed behind the lens, closed, then opened and drawn forward, the two hooks being thus driven into the lens, and holding it securely while it was drawn out of the wound. In some cases the vectis (Weber's) was used in place of the hooked forceps. In some four or five extractions a couple of very fine silk sutures were used after the operation was completed, with the object of bringing about union of the conjunctival flap more rapidly, and of lessening the amount of astigmatism after the operation. The results, however, were not considered sufficiently satisfactory to warrant a continuance of the practice. The small electric lamp was used invariably after the lens had been removed to examine for any soft matter left behind; if any was seen Daviel's spoon was introduced, and an attempt made to remove it.

Discission.—Discission for high myopia was never done for a less degree than 15 or 16 dioptrics. The speculum was used in the majority of cases; a crucial incision was made through the anterior lens capsule with a somewhat sickle-shaped cutting needle, cutting both in concavity or convexity (Knapp). In one of the clinics discission in the above cases was always performed by means of a Graefe knife, held on the flat; that it to say, with the blade parallel to the plane of the iris. The knife was introduced into the anterior chamber, and a single vertical incision made through the whole length of the anterior capsule of the lens if possible. It was held by the supporters of this method that the wound so made in the cornea healed better, and left a slighter scar than that left by the needle.

Discission of secondary cataract was frequently done *per scleram*, but also *per corneam*, with one needle and with two. The operation *per scleram* was performed well behind the ciliary region with a single needle, and gave very good results in cases of obstinate thickened capsules. In no case did any severe reaction follow the operation. In some cases of very much thickened capsule, an incision to remove this was made with a keratome as for iridectomy in the margin of the cornea, the capsule seized with a pair of capsule forceps, as used in extraction, and torn out perhaps with the help of a cystotome. In cases of occluded pupil, the operation with a Graefe's cataract knife as described below — iridotomy — was sometimes performed.

Punction and Linear Extraction.—Punction for removal of swollen-up partially absorbed lens matter, following a previous discission, was done usually on the third or fourth day, when the tension had become slightly raised. A very small incision was made usually at the lower and outer margin of the cornea, with a narrow keratome. Much of the lens matter came out at once with the aqueous, which was let out as gently and as slowly as possible. A Daviel's spoon was then placed in the wound and pressure gently applied backward, more lens substance escaping. After a short pause, during which the anterior chamber was reforming, the spoon was again introduced and more of the lens matter expressed. If necessary a second spoon was used to express the lens from above down toward the wound. The vitreous not infrequently filled the anterior chamber before all the lens matter had been removed. By this operation the period of absorption of the broken-up lens is, it is contended, very much diminished, the risk of acute increase of tension in the eyeball done away with, and very little, if any, corneal astigmatism results.

Syringing Out the Anterior Chamber.—This operation was performed in only one case, in which suppuration had taken place in the anterior chamber following on a cataract extraction. The wound was reopened, and the bent and flattened nozzle of a syringe made for the purpose introduced into the anterior chamber, which was then thoroughly syringed out with a sterilized solution of boracic acid, 1 in 500. This, though performed two or three times, had very little, if any, effect in checking the course of suppuration.

Iridectomy.—This operation was performed either with a Graefe knife or a keratome. The incision with the latter was always begun in the sclera. The iris was drawn into the wound with small iris forceps, and cut off by means of De Wecker's forceps scissors. In two cases following an iridectomy performed in cases of glaucoma, intraocular hemorrhage took place, the lens, vitreous, and entire contents of the eyeball being gradually extruded through the wound, in spite of considerable pressure applied by means of pads and a head bandage. The patient suffered great pain at the time.

Transfixion for Iris Bombé.—This operation was performed with a broad Graefe knife held on the flat, that is, parallel with the plane of the iris (normal), and introduced from the outer side in the cornea. Two incisions were made through the iris on both sides of the pupil, four small holes in all being made. Care was taken not to injure the lens or lens capsule while the point of the knife was passing in front of the pupil.

Operation for Synechiæ.—This operation was performed with a view to loosening adhesions between the iris and back of the cornea. Lang's synechiæ knives were always used. In two cases in which extensive and very firm adhesions were present, most excellent results followed, the iris after the operation being quite unhindered in its movements, and the pupil later on becoming very nearly normal in shape.

Operation against Commencing Staphyloma with Incarcerated Iris.—This operation, which I have twice witnessed, consisted in the trephining of the cornea with the part of the iris involved, and the complete removal of the commencing staphylomatous part of the cornea, with the piece of iris. The loss of substance in the cornea

was then filled up by a piece of healthy cornea of similar size trephined from another eye, which was about to be enucleated. In one case the piece of transplanted cornea, which retained its transparency to some extent, was slightly raised above the surrounding cornea. In both cases the iris was successfully freed, and the cornea given a much greater chance of retaining its shape and nutrition.

Operation for Prolapsed Iris after Injury; Ulcer.—The staphyloma resulting in these cases was carefully punctured by a conical sharp sound, the aqueous allowed to flow away as gradually as possible, the iris then freed all round its adhesions to the corneal wound, drawn out from the wound as far as possible, and cut off with De Wecker's iris scissors. As much of the iris as could be got hold of through the wound was then seized, drawn out, and cut off, until it was in every part completely out of danger of again becoming incarcerated.

Iridotomy.—This operation was always performed by means of a Graefe knife, somewhat narrow, held and introduced through the cornea with the blade at right angles to the corneal surface and with the cutting edge backward, that is, toward the interior of the eyeball and iris. The point was entered through the cornea from below, and advanced in the anterior chamber till it had reached the opposite limit of the chamber. The handle was then brought upward, thus depressing the point and blade, and the iris and occluded pupil cut through; the knife was then withdrawn perpendicularly, cutting the iris completely through immediately below the point of puncture. The very best results were thus obtained, and the reaction was slight. This was only done in cases in which the lens was absent; if any of the lens happened to be present, as in many complicated cases, an attempt was first made to extract it by means of an iridectomy and the usual operation; the pupil, if still occluded, was afterward dealt with in the above manner. Capsulotomy after this method was done also in cases of adherent, thick, secondary cataract.

Optico-ciliary Neurotomy.—The rectus internus was divided and sutured, and the optic and ciliary nerves cut through with a pair of strong, curved, blunt pointed scissors. The eyeball was meanwhile rotated outward as much as possible. The internus muscle was then sutured to its tendon, unless it happened that the bleeding was very great, with great protrusion of the eyeball. The bleeding and protrusion in most cases seemed to be considerable.

Enucleation.—This was always done after the Vienna method. No muscle hook was used, but simply two pairs of large straight scissors, with a small curve, one pair of forceps, a strong catgut suture, and a pair of Desmarre's lid elevators. The operation was done from the left always. In the case of the left eye the externus muscle was first cut through, and the eyeball held in the forceps by means of this muscle's attachment throughout the operation. The internus muscle was last severed, the last after the optic nerve had been divided. With the right eye the internus was the first muscle divided, and the eyeball was held by means of its attachment, the externus muscle being the last cut through, after the optic nerve. A single thick catgut running suture was then placed in the conjunctiva, and just before it was drawn tight and tied, the cavities were well syringed out with corrosive sublimate solution (1 in 1000). Iodoform powder was then dusted in and a dry dressing and head bandage applied.

Mule's Operation.—This was very rarely performed, some three times during ten months. The artificial vitreous used was not spherical, but a flattened, four-cornered, silver-gilt, spheroid, with the corners well rounded off. The cornea and sclera were cut away just behind the ciliary processes, and the scleral cavity scraped out with an ordinary Volkmann's scoop. The interior was well irrigated with corrosive sublimate (1 in 1000), and the wound closed, after inserting the artificial vitreous, by a catgut suture passed through the conjunctiva and sclera at the same time. Dry dressings and a somewhat tight head bandage were applied. Simple evisceration of the globe, without the insertion of artificial vitreous, I never saw performed.

Tattooing for Leucoma. — This operation was performed in the ordinary manner in many cases, but in some the trephine was used to remove the epithelium and upper laminæ of the cornea. A somewhat large trephine, equal to the size of the pupil of the other eye when at rest, was chosen. The piece so marked out was then dissected off, taking as little of the corneal laminæ as possible, and placed on cotton-wool. A few drops of a solution of cocain (five per cent.) were then dropped into the wound in order to stop the bleeding. When this had ceased the India ink was applied with a spatula, and well rubbed and scraped in by the point of a Graefe cataract knife, taking care that the edges of the trephine wound were not notched in so doing. The trephined piece of cornea was then replaced in the wound, but this procedure did not appear very satisfactory, as some bleeding invariably took place under the piece of replaced cornea, raising it up, and it very soon shriveled and dropped off. The resulting appearance, even if this did take place, was very good indeed, the sharply defined margin of the tattooed portion giving quite the appearance of a normal pupil.

Extirpation of the Lacrimal Sac. — This was an operation of every-day occurrence. A cocain injection only was employed. An incision almost vertical in direction was made through the skin on the site of the sac; the wound then kept open by means of Müller's spring wound dilator, and the incision deepened until the internal tarsal ligament was reached. This was then cut through with scissors and the sac dissected free all round; the upper end was raised forward from the bone with forceps and the sac well cleared of all its attachments, and in most cases of inflammatory adhesions. The lacrimal duct, or rather the mucous membrane lining it, was cut through as deeply as possible with scissors, the duct being put on the stretch meanwhile. The cavity thus left by removal of the sac was well scraped out with a Volkmann's small scoop, syringed out with sublimate lotion (1–1000), iodoform dusted in, and the edges of the skin incision united by three or four silk sutures. Union by first intention was as a rule secured; but, if any of the sac had been left behind, this did not occur, and often rendered a second

scraping necessary. This operation was done invariably when ulcer serpens was present. Bowman's sounds were used, but lacrimal styles never.

Removal of Lacrimal Gland.—This was performed in many cases after the above operation. The theory was that the lacrimal gland should not secrete more than could be removed by evaporation. If it did secret more, then it was held to be abnormal and was removed. The operation was performed through the conjunctiva, the cavity being scraped out afterward, and the conjunctiva sutured by two or three catgut sutures.

Knapp's Roller Forceps Operation. — In trachoma cases in which the palpebral conjunctiva was very rich in trachoma granules, the upper lid was everted and cocain was instilled, as well as injected in several places under the palpebral conjunctiva. The granules were then punctured with the point of a Graefe knife, the roller forceps applied, and the contents squeezed out.

Extraction of Steel and Iron Foreign Bodies.—When such were lodged in the interior of the eyeball, and known to be present, the patient was at once taken to the big electromagnet (Haab's), and the piece of metal drawn into the anterior chamber if possible, and then removed by a corneal incision and the smaller point of Hirschberg's magnet. When it was not known for certain whether a piece of metal was present or not, the patient was taken to be tested by means of the sideroscope, which appeared to give only very doubtful results. With Haab's magnet the diagnosis was made absolutely certain, and in many cases the piece of metal could, when it was lodged behind the iris, be actually seen being drawn forward. If the piece of metal were lodged in the posterior chamber, it never came forward throughthe lens, unless there happened to be a hole in the posterior lens capsule, but always slipped round it, till it reached the suspensory ligament, which it tore through, with a sufficiently powerful magnet, and came up against the iris. From this position it was with a little manipulation readily brought forward into the anterior chamber, where it fell. Since this magnet has been in use, it has never failed to extract a splinter of iron or steel from the interior of the eyeball, no matter how deeply it has been embedded.

Sclerotomy.—Both anterior and posterior sclerotomy were constantly performed. Posterior sclerotomy after Priestley Smith's method was invariably performed on glaucomatous globes, in which intra-ocular hemorrhage might be expected to occur if an iridectomy were undertaken.

Plastic Operations.—Of the many and various plastic operations I will not attempt any description, as the number is far too great, due to the great amount of trachoma, the resulting scarring and deformities being relieved, or attempted, by all the various typical and atypical operations which suggest themselves. Thiersch's skin-grafting is a very favorite method in the case of extensive burns.

Number of Operations.—Of the total number of operations of all kinds performed, some idea may be gathered from the fact that between November 1, 1897, and July 9, 1898, 1499 operations were performed and written up in the operation-books, 400 of which were cataract extractions. This number does not include such operations as scraping hordeola, meibomian cysts, etc.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 6, 1898.

The President, E. G. Janeway, M.D., in the Chair.

The paper of the evening, entitled

NOTES ON SURGERY IN THE RECENT WAR

was read by Major William Duffield Bell, Surgeon of the Seventy-first Regiment, New York Volunteers. (See page 488.)

Discussion.

Dr. Joseph D. Bryant: Although I was not on the battle-field, I have had some experience with these cases, having come in contact with the patients after their transportation to this city, and I have been struck by the marked characteristic of the wound made by the Mauser bullet—the widely differing effect which it has upon the hard and soft parts. This was particularly brought to my notice by two instances. In the first the man received a bullet in the upper third of the humerus. It made its exit posteriorly and plowed through the chest-wall. This happened four weeks before I saw him. The wound in the arm had closed, with no history of the escape of pus or bony fragments, and there were no evidences of such having taken place. There was, however, considerable thickening of the parts, indicating that there had been not exactly splintering of the bone, but what might be called *pulverization.* There was some union—enough to obscure any evidence of exposed bony fragments—but false motion was well marked. But little or no pain was present. The wound of the superficial soft parts of the thorax made by the bullet in its exit had not healed. It looked as if it had been made with a red-hot iron, or, to put it more clearly, it resembled a slough with a distinct line of demarcation, the edges of the wound being ragged and torn. This is one of the characteristics of the Mauser bullet. The patient eventually made a good recovery.

The second case was that of a lieutenant of the regular army, who informed me that he was one of the first wounded, and consequently one of the first whose wounds were dressed, and, therefore, considered himself especially fortunate. He was wounded in the upper third of the femur, the ball passing through the limb and grazing the opposite one after making its exit. Four weeks had elapsed since the injury when he came under my care. There was about one and one-fourth inches of shortening and considerable false motion, which I accounted for by the division of the soft parts and also by the fact of his being brought from Cuba on one of the transports. He told me that when the wound was received there was but little hemorrhage, comparatively speaking. I had the limb put up in plaster of Paris and kept there for four weeks, at the end of which time the bone seemed to be firmly united. The patient was cautioned to be careful, but within forty-eight hours he began to complain of pain

at the seat of injury. Later this pain increased and false motion was detected. This may be explained by the bad physical condition of the man, who had been subjected to the detrimental influence of camp-life at Santiago, and it may also have been due to extensive injury to the bone.

DR. JOHN H. GIRDNER: I would like to ask the author if he noticed any difference in the character of the wounds caused by the Mauser bullet fired at short and long range.

DR. BELL: Of course the wound is different when the bullet is fired at short range. At one time we sent word to the Spaniards that if they did not stop using explosive bullets we would use them ourselves. They sent back an answer to the effect that we must be already using them ourselves, as evidenced by the wounds their soldiers were receiving. The effect of a bullet fired at 500 yards differs from that fired at 800 yards. At El Caney nearly all of the wounds were received at 400 yards, and at San Juan before the troops got within 800 yards of the enemy. In the case of the wounds received at El Caney the bones were splintered—in some cases to a state of pulp. At San Juan the bullets passed through a bone without splintering it. In one case a man was shot through the head, the bullet entering behind the ear, through the mastoid process, and coming out near the spine. He bled profusely, but was all right within a week. Wounds of the abdomen were remarkably well borne. The patients did not suffer from shock, no operation was performed, yet the patients invariably recovered. In one case which came under my observation there were eight perforations, and yet the man was able to walk four miles to the hospital. Operation was proposed, but as there was no shock and no hemorrhage it was suggested that we wait ten or twelve hours. During this time the patient disappeared. He was walking about three days later and has had no trouble since. Wounds of the lung were followed by profuse expectoration but no other symptoms presented, unless there was also fracture of the ribs causing perforation.

A peculiarity of the Mauser bullet is that it never lodges in bone but always passes through it. Even a spent ball will do this. It frequently passes through one man and strikes another, and even a third. It makes a very pretty wound. I know of one case in which a man was shot through the liver and another in which the bullet passed through the thorax, and both men recovered. The wound caused by the Mauser bullet is in striking contrast to those made by the explosive bullet fired at short or long range from a Springfield rifle. When the latter strikes a tree it digs a hole in it. When it strikes a man's head it leaves a wound like that make by a shell.

In regard to the absence of hemorrhage in injuries of the soft parts, this is explained by the fact that the blood-vessels seem to recede from the bullet. In one case in which a man received a bullet in the groin, passing through the hip back of the joint, it seemed as if it must have severed the femoral artery, but it was found that the vessel had shrunk into the wound. This peculiarity was noted by five or six surgeons. I have also noticed that wounds of the soft parts heal at once. When the first dressing is removed on the third day healing has already begun.

DR. MONA LESSER: While in Cuba I had 181 cases of this kind in my charge. Of these 161 required surgical operations of more or less importance. The rest were clean wounds, either through the skull, the thorax, the abdomen, or the extremities. Among the most remarkable were 18 men who were shot through the skull. In one instance the man was shot through the parietal bones, causing profuse hemorrhage and the patient was brought to the hospital paralyzed in both the upper and lower extremities. He was immediately trephined and much to the surprise of all, he was able to use his arms and legs, showing that the trouble was due to pressure from blood-clots. I have since learned that the patient came to this city where he was operated upon by a prominent surgeon and died. Another interesting case was that of an officer who is now superintendent of the West Point Academy. He received a bullet which entered a little below the right eye and made its exit on the left cheek. He was brought to the hospital blind. The muscles surrounding the right eye were completely paralyzed and he could barely distinguish a light when it was held directly in front of him. He has since recovered the use of one eye. One of the officers of the Ninth Cavalry received a bullet in the head which fractured the parietal bones. He was dazed when brought to the hospital but made a good recovery after the depressed bone was raised. The great majority of the wounds were clean and the only dressing applied was a piece of plaster. I saw ten or twelve cases in which a bullet had passed directly through the abdomen from before backward or from side to side. In two cases intestinal hemorrhage occurred on the first or second day but in each instance the patient recovered. I also saw several cases—two or three—in which the bullet passed through the neck. These were clean wounds. Wounds of the extremities were usually accompanied by compound comminuted fractures, and this was always the case if the bullet was fired at close range. The treatment given was very simple and recovery ensued except in those cases in which the bone was reduced to a pulp. I saw one such case operated upon by Dr. Nancrede. It is a remarkable fact that of the 1415 patients treated at Santiago during the first week in July only four had died up to July 7th. Surgical fever was almost unknown in the camp. In cases in which a bullet was received in the forearm or leg, one bone of the extremity was badly fractured and the other very little. It was generally necessary to remove small portions of bone, leaving those which were attached to the periosteum, and the patients did remarkably well. The American soldiers seemed to do better than the Spaniards. Those of the latter who received their wounds in the naval battles were very badly injured. There were no clean wounds among them. Resection was not possible—it was either amputation or nothing. Among those wounded on the field there were many in whom large vessels were injured. These were ligated and most of the patients recovered. Twelve such cases were treated between July 2d and 3d. Five of these, Spanish soldiers, died within the first twenty hours—one from tetanus, one

from yellow fever, and three from septicemia. They had been lying several days unattended. The most remarkable part of it all was that most of the injured were able to walk miles to the hospital with nothing but a little pad on their wounds. I am sure that many hundreds would have died but for these little pads with which their wounds were dressed on the field. The Spaniards did not have these pads. Taking it all together we must come to the conclusion that the Mauser bullet, when fired at long range, is a very humane one. I went to the war expecting to see a great deal of operating, but I saw very little. There were a few resections done at Siboney and I saw six amputations—two of the lower extremity at the thigh, two below the knee, one of the arm, and one of the hand. Most of the wounds were not of a severe character and required the most simple treatment. Recovery generally followed if this treatment was promptly given on the field. Major Bell has told you how well this was done, and I can only add that it is impossible to give too much praise to the army and volunteer surgeons for the good work they did.

THE PRESIDENT: I would would like to ask the author whether he saw much tetanus among the wounded. I have been told by Cuban medical students that idiopathic tetanus is not uncommon in their country,

DR. BELL: I saw no tetanus in Cuba but I believe a case was reported as occurring in Florida. That we did not have it in Cuba is probably due to the great care with which wounds were treated on the field. Antiseptic solutions were prepared with boiled water and in all the field hospitals scrupulous cleanliness was strictly carried out. The antiseptic pads which were applied on the field were also of great service in preventing wound infection.

DR. DANIEL M. APPEL, U. S. A.: I have had charge of the sick and wounded who were sent to this city on the transports. They were immediately sent to the various city hospitals and I have seen them constantly. They are beautiful cases so far as the results are concerned. The few deaths which have occurred were of men wounded in the abdomen, upon whom operation was necessary on account of extensive laceration of the viscera, such as the liver, and in whom a fatal result was to be expected.

AMERICAN PUBLIC-HEALTH ASSOCIATION.

Twenty-sixth Annual Meeting, Held at Ottawa, Canada, September 27, 28, 29, and 30, 1898.

THE President, DR. CHARLES A. LINDSLEY of New Haven, Conn., in the Chair. The Association met in the Railway Committee Room of the House of Commons.

DR. JOHN L. LEAL of Paterson, N. J., read a paper, entitled

AN OUTBREAK OF TYPHOID FEVER DUE TO AN INFECTED WATER-SUPPLY.

He dealt with the pollution of water as supplied to the residents of Paterson. This outbreak established the fact that the germs originating from a single case of typhoid fever might infect even a large body of water, so as to reproduce itself among those dependent upon the same water for their public supply, even though the supply be taken at a point some distance from the focus of infection.

THE CAUSE AND PREVENTION OF INFECTIOUS DISEASES,

was the title of a paper read by DR. PETER H. BRYCE of Toronto. He said that infectious diseases must be divided according to their mode of causation, their growth and development. With reference to methods for suppressing outbreaks of diphtheria in a community, in a number of municipalities in Ontario where the disease appeared, principally among school children, the practice was introduced of a morning visitation by the Sanitary Inspector to all the public schools to obtain a list of the children that were absent. The homes of these were promptly visited and when any evidence of malaise and sore throat was present the parents were at once required to send for a family physician and have a swab taken and forwarded to the medical officer by the afternoon. These were sent at once by mail to the laboratory and the patient isolated, until an answer by telegraph of the result of the examination was received. When the cases proved to be diphtheria, the patient was isolated until further examination proved the freedom of the throat from bacilli. The children of the household were kept from school and the public, and the homes subsequently disinfected with formaldehyd when the children had not been removed to the hospital.

ANNUAL ADDRESS OF THE PRESIDENT.

DR. LINDSLEY said that the primary and ultimate purpose of the Association is the protection and preservation of public health. He dwelt at length upon the rapid progress that medical science has made during the past few years. Provincial, State, and local boards of health are coming to be recognized everywhere as necessary forces for the safety and well-being of all civilized communities. The movement has gained an impetus which cannot be resisted. It must go on, nurtured, sustained, and guided in its progress by the skill, judicious enterprise, and intelligent energy, so characteristic of the people of North America, until, in practical utility and successful results, it will have no superior among the nations of the earth.

DR. HENRY B. HORLBECK of Charleston, S. C., presented the

REPORT OF THE COMMITTEE ON THE ETIOLOGY OF YELLOW FEVER.

Reference was made to the labors and experiments of Sanarelli. This scientist claims that he has found the bacillus icteroides in fifty-eight per cent. of the cases examined by him, and believes that the reason of his non-success in finding it always is due to incidental causes. Dr. Horlbeck referred to the investigations of Drs. P. E. and John I. Achinard of New Orleans, who have studied the subject of yellow-fever in relation to diagnosis by the Widal method. In fifty cases of yellow fever, agglutination with cessation of motion was obtained in more than seventy per cent. of the cases, the reaction being as characteristic as in typhoid-fever cases. The work of these

gentlemen demonstrates the practical value of serum diagnosis. It may be utilized as early as the second day. The dried-blood method of Dr. Wyatt Johnston was perfectly satisfactory. The serum diagnosis of yellow fever should be instituted in all countries wherein the disease may exist endemically, or which may be occasionally visited by epidemics. It is especially valuable at the beginning of epidemics in the diagnosis of early and doubtful cases. While the bacillus of Sanarelli is not the inevitable cause of the disease, it is still of sufficient importance to warrant its closer study.

DR. E. LICEAGA of Mexico, said that yellow fever has been known to be transmitted through the bagging that carries, corn, sugar, and coffee. It has also been transported by the clothing of persons who had been attacked by the disease. Another material which serves to propagate yellow fever is the ballast which is shipped by the vessels in Vera Cruz after having landed their cargo. The propagation of yellow fever through the medium of water is not well established, although it is a probable cause. The general conditions that favor the transmission of the disease are humidity, heat, and want of light and ventilation. Mosquitoes are known to carry the germs of the disease.

DR. ERNEST WENDE of Buffalo, read the

THE REPORT OF THE COMMITTEE ON THE CAUSE AND PREVENTION OF INFANT MORTALITY.

He said that several scarlet fever and diphtheria epidemics have been averted in Buffalo by promptly tracing the infection to a particular milk-supply. Most satisfaction has been found in the general condemnation of the long tube, death-dealing nursing-bottle. Buffalo, through its city health department, has interdicted the use of the long rubber tube, as a consequence of which a suit is now pending in the courts to test the validity of such action, this suit being prompted by commercial interests. In preparing for this litigation, in order to be able to demonstrate the danger of such nursing-bottles and the justification for suppressing them, the department of health has resorted to a series of microscopical, bacteriological and chemical investigations, which have revealed innumerable bacteria of varied morphology.

SOME OBSERVATIONS FROM PRACTICAL EXPERIENCE WITH BOVINE TUBERCULOSIS IN NEW HAMPSHIRE.

This paper was read by DR. IRVING A. WATSON of Concord, N. H. He gave a brief history of the official recognition of bovine tuberculosis in New Hampshire, and presented the following deductions: (1) That it is impossible to eradicate bovine tuberculosis, but that it may, without inflicting too great a burden upon the State be reduced to a degree that will subserve the interests of the stock raisers, and likewise protect the public health. (2) That but a very small percentage of animals infected with tuberculosis in any way endanger the public health, and that the indiscriminate slaughter of the cattle reacting to the tuberculin test is wholly unnecessary, inasmuch as many of them either recover or the disease is permanently arrested. (3) That a proper sanitary condition of stables and stable enclosures would do more toward preventing the spread of bovine tuberculosis than any other measure that can be adopted. (4) That the danger of infection from this disease may be reduced to very small proportions if not wholly eradicated by sanitary measures, inspections, and physical examinations by the State in cooperation with local authorities. (5) That such inspections, once inaugurated, can be maintained without an expense that would be burdensome to the State.

REPORT OF THE COMMITTEE ON DEMOGRAPHY AND STATISICS IN THEIR SANITARY RELATIONS.

The first part of this report, which was read by the Chairman, DR. WILBURM of Michigan, recommended the adoption of the Bertillon system of classification of causes of death, in accordance with the resolutions previously offered and adopted. Reliable and thoroughly comparable mortality statistics are absolutely essential for the use of sanitarians, and deductions based upon them are recognized as being of the greatest practical importance in public-health work. The formation of a plan of international union of the countries using this system occupied a considerable part of the report. The plan provides for consultations of pathologists, sanitarians, and all persons making use of mortality statistics, as well as the registration offices.

The system of classification and plan of revision were adopted by the Association, and the members of the National Commission for the countries represented were appointed.

LEPROSY IN MINNESOTA.

DR. H. M. BRAKEN of Minneapolis, read this paper, in which he called attention to the following facts as emphasized by the records:

1. The impression that leprosy immigrants from the Scandinavian peninsula are all from Norway is a wrong one, as five of eleven lepers whose cases were placed on file by the board during 1897 and 1898 were from Sweden.

2. The feeling that physicians can quarantine against lepers by watching immigrants is an unsafe one. The family history of all immigrants from the country where leprosy prevails should be secured before they are allowed to embark for America, and no member of a leprous family should be permitted to land on our shores.

3. It would appear that the conditions antagonistic to the spread of leprosy in Minnesota are also opposed to sterility, as borne out by the families of several lepers, some of these having had many children.

4. It is quite possible for leprosy to die out in certain favored sections of the country, such as Minnesota, without segregation, provided the importation of lepers is discontinued.

5. Even in Minnesota one has but to visit some of these lepers to feel that segregation should be insisted upon in all cases. One cannot but feel, on entering a filthy home and seeing a leprous mother careless in her habits, that the children are not safe.

6. Segregation in single States is not practicable. It tends simply to drive lepers from States enforcing such a practice to those that are not carrying out the system.

7. A Federal home should be provided for these un-

fortunates. They could thus be cared for more economically and more satisfactorily than through any State provision.

8. In spite of all precautions taken, there will be some leprous individuals in this part of the world for many years to come. The Scandinavian peninsula does not furnish all leprous individuals found in the United States.

Two papers were presented on

FLIES, FROM A HYGIENIC STANDPOINT.

Abundant evidence was adduced to show that diptera are active agents in the spread of epidemics and of contagion. They are also known to be important causative factors in the spread of typhoid fever and dysenteric diseases.

In the transaction of its routine business the Association elected sixty-six applicants to membership, the majority of whom were from Ottawa.

Dr. C. L. Wilbur of Lansing, Mich., offered resolutions, which were adopted, recommending that a plan be incorporated in the act to provide for the taking of the next United States census whereby reliable vital statistics may be secured for the non-registration States. The Association recommended the Bertillon classification of causes of death, and urged that it be adopted by all registrars of vital statistics in the United States, Canada, and Mexico as soon as the change from the systems now in use can be conveniently made.

The following resolutions were offered, referred to the Executive Committee, and subsequently adopted by the Association:

By Dr. Geo. H. Rohe:

Resolved, That the Committee on Public-Health Legislation be continued; that it be authorized and requested to proceed along the lines of work already begun; that the Association reaffirms its endorsement of the creation of a National Department of Public Health.

By Dr. A. L. Gihon:

Resolved, That a committee of seven be appointed by the Chair to wait upon the President of the United States with a view of obtaining a bacteriological commission to go to Havana to study the cause and prevention of yellow fever.

By Dr. A. Walter Suiter:

Resolved, That this Association recommends that public-health authorities in general exercise every possible means to effect the complete discontinuance of the use of the so-called long-tube nursing-bottle, which is so largely a contributing factor in infant mortality.

By Dr. U. O. B. Wingate:

Resolved, That a committee of five be appointed by the Chair for the purpose of drafting and presenting to this Association for adoption a definition of the term "epidemic" for the guidance of health authorities in executing such laws as call for the declaration of the presence of an epidemic.

By Dr. Henry B. Horlbeck:

Resolved, That the Association call the attention of the Government of the United States to the presence of leprosy in this country. This Association would urge upon the United States Government the necessity of establishing a leper home or colony, similar to such institutions as now exist in Canada and Mexico, where such persons can be segregated, and in this manner the general public may be protected, and, at the same time, these sufferers be afforded a proper home and medical care.

The following officers were elected for the ensuing year: President, Dr. George H. Rohe, Sykesville, Md.; first vice-president, Dr. Henry Mitchell, Asbury Park, N. J.; second vice-president, Dr. J. E. Monjaras, San Luis Potosi, Mexico; secretary, Dr. C. O. Probst, Columbus, Ohio; treasurer, Dr. Henry D. Holton, Brattleboro, Vt.

Minneapolis was selected as the place for holding the next meeting, the time of which will be in November, 1899.

REVIEWS.

Guide to the Clinical Examination and Treatment of Sick Children. By John Thomson, M.D., F.R.C.P., Extra Physician to the Royal Hospital for Sick Children, and Lecturer on the Diseases of Children in the School of Medicine of the Royal Colleges, Edinburgh. Illustrated. Philadelphia and New York: Lea Brothers & Co., 1898.

The object of this work, as stated in the preface, is to "supply to practitioners and senior students practical and useful information, which taken along with that contained in a text-book on practice of medicine, will be a help to them in the study and treatment of sick children." This idea is faithfully carried out, and the book will be welcome to a large class of readers. The larger amount of space is devoted to the examination of sick children. This part is full of valuable information, and contains many practical hints. Everywhere there is evidence of the close observation of the author. After this follow some chapters on the diseases peculiar to, or peculiar in, infancy.

The discussion of the diagnostic points of hereditary syphilis, of idiocy, and cretinism are especially worthy of perusal. We miss a consideration of some of the more common diseases of the new born. There are very good chapters on infant-feeding, the dosage of drugs, and therapeutic methods. The articles on gavage and lavage are very complete. The volume ends with a discussion of food disorders.

The language of the text is very clear, and the book is freely illustrated with reproductions of photographs which show clearly the desired points.

Lectures on Tumors. By John B. Hamilton, M.D., LL.D., Professor of Surgery, Rush Medical College and Chicago Polyclinic; Surgeon to Presbyterian Hospital; Consulting Surgeon to St. Joseph's Hospital, etc., Chicago. Third edition. Philadelphia: P. Blakiston's Son & Co., 1898.

It is a surprise to us that a book of this kind should have reached its third edition, for we cannot understand the necessity of its existence or the demand for its sale.

The book comprises a series of lectures to students on the subject of tumors, giving the symptomatology and treatment of each variety, and mentioning in detail the clinical history of several interesting cases, many being well known in literature, and some being personal observations of the author. The entire book is written in the free and easy lecture-room style, and to those interested in the general subject of tumors and familiar with them, may prove of some interest, particularly as to the clinical pictures described. But as a work dealing with tumors in a scientific manner, and as a work of reference it can hardly be recommended as a guide for the student.

ELEMENTS OF HISTOLOGY. By E. KLEIN, M.D., F.R.S., Lecturer on General Anatomy and Physiology, and J. S. EDKINS, M.A., M.B., Joint Lecturer and Demonstrator of Physiology in the Medical School of St. Bartholomew's Hospital, London. Revised and enlarged edition. Philadelphia and New York: Lea Brothers & Co., 1898.

KLEIN'S "HISTOLOGY" is too well known to teachers and students to require any special introduction, and it would be superfluous to review it *in extenso*. The work has now passed through five editions, and the present volume brings the subject well up to date. Many of the chapters have been carefully revised, and that upon the central nervous system has received particular attention. We are acquainted with no small work in English that deals with the subject in a more clear and comprehensive manner or that satisfies the needs of the student to better advantage. More advanced workers will even find it useful in some instances as a book of reference.

Many new illustrations have been added, and the glazed paper upon which the book is printed is a decided improvement over the early editions. Altogether the work can be highly recommended, and we congratulate the authors and publishers in giving us a book so well equipped to satisfy the requirements of all students.

MEDICAL DISEASES OF INFANCY AND CHILDHOOD. By DAWSON WILLIAMS, M.D., Physician to the East London Hospital for Children. With eighteen illustrations. Philadelphia and New York: Lea Brothers & Co., 1898.

THIS treatise is a good, short exposition of our present knowledge of the medical diseases of children. The descriptions of symptoms are quite full, and the treatment recommended will meet general approval. The accounts of rubella, tuberculosis, infective arthritis, acute thyroiditis, congenital laryngeal stridor, and constipation are excellent. The bacteriology of the infectious diseases is not well detailed. Bacilli are mentioned as probably causing measles and smallpox, but neither the Koplik-Czaplewski bacillus of pertussis, the diplococcus of parotitis nor the intracellular diplococcus of meningitis is mentioned. Under rubella there is an interesting account of supposed cases without the rash. The consideration of the treatment of laryngeal diphtheria is very incomplete.

The physical signs of pulmonary disease in children are very well described. The gastro-intestinal diseases "are classified according to clinical features"; but the order which is followed is curious. The diseases are, however, very well pictured, and the article is illustrated by Baginsky's photomicrographs. The pathology of renal diseases is not clearly given. The chapters on nervous diseases are very instructive, especially those on functional disturbances. The defects in the book are very few, and it will be of great service to those entering upon the study of pediatrics.

A TREATISE ON THE SCIENCE AND PRACTICE OF MIDWIFERY. By W. S. PLAYFAIR, M.D., LL.D., F.R.C.P., Emeritus Professor of Obstetric Medicine in King's College, London. Seventh American, from the ninth English, edition. Philadelphia and New York: Lea Brothers & Co., 1898.

THE old student of Playfair's "Midwifery" will find much of his favorite reading matter missing and much that is new and strange in this volume. The eminent author has, to use his own words, "endeavored to celebrate the fact of his work having attained its majority by a very thorough revision of the text," the first edition having been published twenty-two years ago.

It is impossible to record all the changes that have been made. Especially noteworthy are the chapters on conception and generation and the anatomy of the fetus, which have been rewritten in harmony with modern embryologic thought. The chapters on diseases of pregnancy have been made consistent with the pathologic knowledge of to-day and the treatment of difficult positions is in accord with the latest accepted teachings. The use of the forceps is admirably discussed and promulgates the author's well-known scientific views. Saline infusion is not given that prominence or preference to blood transfusion, which, in our opinion, its merits deserve. The question of infant-feeding is treated more scientifically than in earlier editions.

With these few notes the reviewer directs attention to this old classic among works on obstetrics, now in new form and new dress, and feels that it is destined to remain, as it long has been, the favorite among books of its kind.

THERAPEUTIC HINTS.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIII. NEW YORK, SATURDAY, OCTOBER 22, 1898. NO. 17.

ORIGINAL ARTICLES.

ERGOT IN CHRONIC MALARIA.[1]

BY A. JACOBI, M.D., LL.D.,
OF NEW YORK;
CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN COLUMBIA UNIVERSITY.

THESE notes are written exclusively for clinical purposes. That is why a few words on the active principles of ergot may suffice. They are sphacelinic acid, cornutin, also trimethylamin, vernin, and ergotinic acid. Trimethylamin gives rise to cerebral spasms which may become tetanic. It increases reflex irritability, and according to Gaethgens, accelerates, by irritation of centers located in the medulla oblongata, respiration and blood-pressure. Vernin, which was found by Schulze and Bosshard, is a new xanthin substance with effects similar to those described above. Sphacelinic acid (spasmotoxin, sphacelotoxin) so called by Kobert who first studied and named it, when absorbed in the intestine causes a hyaline degeneration of the blood-vessel walls, which first contract and finally dilate, also coagulation inside the vessels with consecutive gangrene. In proportion to the doses taken it causes paresthesia, alopecia, falling out of the nails, and gangrene of the skin or of the extremities. Fortunately, it is easily decomposed, so speedily indeed that ergot a year old contains none at all. The effective principle is cornutin, found and named by Kobert. What Tanret called ergotinin is chemically identical with it, but does not equal it in efficiency when prepared according to Kobert. It is easily decomposed when exposed to light or air. There is but little of it in ergot, all the alkaloids forming but 0.2 per cent. of the drug. It irritates the medulla oblongata, contracts arteries, increases blood-pressure, and contracts the unstriped muscular fiber in general. It is employed as a citrate or a chlorid. Kobert speaks of it as enclosed in capillaries holding 0.005 for subcutaneous use, or in pills of 0.002. In Merck's index, "cornutin" and "cornutin citrate" are enumerated. In poisonous doses it causes convulsions and contractures, also toxic polyneuritis, such as follows overdoses of arsenic, lead, phosphorus, alcohol, or mercury. Ergotinic acid, called sclerotinic acid in its impurer state, lowers the blood-pressure in animals. Before knowing better, I recommended it even in my "Therapeutics" for subcutaneous injections to obtain the effect of ergot; that was a serious mistake. In the intestinal tract it is decomposed, and under the skin it is painful and irritating.

All of these constituents lose their power while in the ergot, from month to month. It should be gathered before the rye is perfectly ripe for harvesting, but generally is not. The decomposition of the grain is mainly due to its large percentage (39) of fat; that is why a salutary effect is often missed and the opinions in regard to the efficiency of the drug differ. The effect of the extract or fluid extract depends on the retention of the cornutin. All such preparations as are deprived of the substances soluble in alcohol, are deteriorated thereby, for it is the active alkaloids that are soluble in alcohol. In the fluid extracts the alcohol should be strong enough to hold the alkaloids and dilute enough to dissolve but little of the fat. As far as I am concerned, I have employed for internal use, whenever possible, the solid alcoholic extract of the pharmacopœia. It seemed to me to give better results than even Bonjean's ergotin, which has been in the market since 1842. At all events, the value of ergot preparations is in their undecomposed alkaloids; everything else is either indifferent, disturbing, or injurious.[1]

The effect of ergot and its preparations, when given in medicinal doses, is mainly spent on the unstriped muscular fibers. Its effect on the uterus has been known and used and abused a long time. The muscles of the vagina were found to be influenced by it by Swiecichi.[2] That is why I felt encouraged more than forty years ago to administer it in conditions of hyperemia and of the acute and subacute inflammations of such organs whose blood-vessels are not entirely or almost deprived of muscular layers. The media of small arteries has unstriped muscular fibers. There are several of these layers in the larger ones, which besides are supplied with elastic fibers. This structure is uniform in all the arteries of the body. The veins, however, exhibit more startling differences, nowhere more than in the tunica media. It consists of circular muscular fibers, elastic network and fibrillar connective tissue, is best developed in the v. poplitea and the other veins of the lower ex-

[1] Read at the Annual Meeting of the American Climatological Association at Bethlehem, N. H., September 1, 1898.

[2] Quoted by Kobert, "Intoxicationen," p. 185, 1893.

tremities, less in those of the upper extremities, still less in those of the abdominal cavity. It is *absent*—and here is an important point—*from the veins of the pia and dura mater*, of the retina and the bones, the vena cava, and all the veins emanating from the capillaries, where the media consists of transverse and oblique bundles of connective tissue only.[1]

As I said, the veins of the pia and dura have no muscular fiber in the media; moreover, in the cranial cavity they are long and distant from their arterial pressure-supply. That is why I am never surprised when the employment of ergot in brain disease is wholly futile. Circumstances are different in connection with the spinal canal. The veins of the cord and its membranes are no better supplied with contractile elements than those of the cranial cavity; but because of their shortness they are under the immediate influence of blood-pressure. That is why ergot, so useless in brain disease, is perfectly adapted to cases of spinal hyperemia, or to acute, or subacute spinal inflammation.[2]

The practice of employing ergot in spinal cases was gradually developed. In a report published in the *New York Medical Monthly*, during the years 1860 and 1861, on my clinic of the diseases of children in the New York Medical College, then in existence, you may find a few of my earlier cases in which I employed ergot for the purpose of contracting blood-vessels and relieving hyperemia and inflammation in spinal diseases.

Number 68 is a case of acute poliomyelitis; number 122, one of spinal meningitis; number 167, one of spinal hyperemia. So far as I know they are the first I published after some years of experience with the drug. In regard to the latter disease my information was obtained from a friend who at that time was stationed at the Emigrant Hospital of Ward's Island, Dr. Francis Simrock. Some histological considerations encouraged me besides in employing it in this way. The capsule of the spleen consists of dense and hard connective tissue, unstriped muscular fiber, and an elastic network. It sends off numerous processes, leaf- and string-like layers, into the interior of the spleen, thus forming a coherent network which contains the pulp. This network also contains, besides connective tissue, copious unstriped muscular fibers. Thus it seems there is no organ in the animal economy more amenable to the action of a muscle-contracting agent.

The employment of ergot in moderate doses has no dangers under most, ordinary circumstances. I have used it these forty years extensively, for weeks and even months in succession, without a single case of intoxication. The latter has frequently been observed in all countries of Europe, mostly in the past. If we hear of epidemics or endemics of ergotism, there are but few countries in which they are often met with, *viz.*, Spain, and still more, Russia. With the increase of civilized agriculture and a slight improvement in the general condition and nutrition of the population, the average of good rye increases, that of ergot decreases. In every harvest of corn there is some ergot; one per cent. is common and not attended with danger. But when a population is starved and subjected to malaria and other infectious diseases, and unclean and sleepless from hard work, starvation, and anxiety, and when they are fed on rye with a large percentage of ergot, and particularly when it is of recent growth, during and a very few months after cutting, ergotism may make its appearance.

There is danger in poisoning only, not in medication. In connection with malaria there are two organs we have to consider when medicating, the blood and the spleen, the former because it contains the sporozoa, the latter because of its sponge-like mass in which it harbors the infected blood and serves as a receptacle of dangers. It appears that a direct effect on the blood or on the plasmodia is not required for a cure, but that gradually the restoration of the spleen to a fairly normal size, forcing the stagnating blood into a normal circulation with progressive elimination of the plasmodia is sufficient to open the gates to recovery. That is what I believe I have often done by giving ergot in malaria.

The uncertainty of the effect may also be due to the fact that most preparations of ergot contain both ergotinic acid, which lowers arterial pressure, and cornutin which contracts the arteries. All of this should impress us with the necessity of using the alkaloid cornutin when it is obtainable. Even this substance should be used with great care, for in-

[1] Ph. Stoehr "Histology," seventh edition, p. 91.

[2] In hemorrhages, such as those of the lungs, ergot has long been used by some with great confidence, by others with indifferent success. Among the latest preparations is ergotinol, of which 1 c. c. corresponds to a gram of extract of ergot, which Vosswinkel eulogizes highly in pulmonary hemorrhages when used subcutaneously. Some think highly of ergot in all sorts of inflammatory processes. There is Croq of Brussels, for instance, who employs it in tuberculosis. In his opinion the tendency of tuberculosis is rather that of getting well, unless complicated by inflammatory processes to counteract which no medication seems to be more indicated than that of ergot. Certain forms of spermatorrhea and nocturnal enuresis connected with muscular incompetency of the sphincter are frequently benefited. Here its effect may be the direct one on the unstriped fiber, or on the spinal center of the sphincters which must be taken to be present in the lumbar cord along the uterine and spermatic centers. It has been given in Graves' disease for the same reason, not to speak of, for reasons unintelligible to me, its use in non-pancreatic diabetes mellitus, sea-sickness, and whooping-cough. In the paralytic form of hemicrania it has been highly recommended, and may be all of us have employed it. In tabes, spastic spinal paralysis, in progressive bulbar paralysis, it has been used because of the supposition that the anatomical lesion is attended by dilatation of blood-vessels. The results are but few or none. At all events, no physiological effect can be expected except in the initial stages when there still is or may be spinal congestion.

stance, in hemorrhage, which may be increased by heightened blood-pressure.

CASE I.—A Hungarian boy, aged five years, just arrived in the country, October 10, 1859. Had fever and ague, mostly quotidian attacks, at his home. On the ocean he was better, *viz.*, now and then he had a day without an attack. He was pale, waxy, with extensive hemic murmurs and with albumin in the copious and watery urine. His spleen extended nearly to the spina anterior superior. Had regular daily attacks with great prostration, in spite of quinin and Fowler's solution. Of the former he took from 6 to 12 grains daily. Being previously constipated his bowels had been attended to. Not being acquainted with the fluid extract—perhaps it was not even in the market[1]—I gave him an infuso-decoction, prepared with sulphuric acid, of half an ounce of ergot in 10 ounces of water, of which he was to take one-half tablespoonful three times a day. There being no improvement he took, after four days, the same dose five times a day. When I saw him ten days later he had been without an attack three days. The doses were continued five days, then for five more days four daily doses were given, and thereafter but three. During all this time he had no attacks of fever, albumin became less, but his spleen was still as large as before under percussion and palpation. Finally he was removed from South Brooklyn where Gowanus Bay was as pestiferous at that time as the shores of the River Theiss, and gradually with the use of iodid of potassium, iodid of iron, and the occasional resumption of ergot, he improved. After a year I saw him again, looking well but pale, with no albuminuria, hardly any murmur, but his spleen still palpable 3 centimeters below the border of the ribs.

CASE II.—His brother, sixteen years old, gave me a new experience. He had the very same symptoms exhibited by his brother—hydremia, tumor of the spleen, etc., without albuminuria and without the history of chills. For the latter reason he had taken no medicine whatsoever. After purging him gently I ordered the same medicine to be taken in tablespoon-doses four times daily. Two days after beginning his treatment he had a very violent chill followed by perspiration; no temperature was taken, as he was miles away. He had another violent attack the next day, a milder one a few days after this, and then no more. He was treated like his brother, with the same slow but finally satisfactory result.

CASE III. — A. W., male, fourteen months old. Was seen by me October 1, 1880. Was breastfed until half a year previously, then fed on mixed food. Had diarrhea in the summer, and fell ill with pneumonia of the right side a fortnight before I saw him. This was watched carefully; I found but few remnants of it. But in the beginning of the second week the baby was taken with a convulsion, high fever and vomiting, lips and fingers were bluish. After a few hours the condition improved, but on the following day, blue nails, high temperature, followed by apyrexia, and great debility were noticed. No return of pneumonia; no nephritis. Quinin was given in repeated doses for several days. No convulsion returned, but there were temperatures up to 102° and as low as 97° F. every day. The urine was pale all the time; more was passed during the high temperature, none during apyrexia. On October 1st this condition, of somewhat elevated temperature every day, which lasted a few hours, continued in spite of from 30 to 40 cg. of sulphate of quinin. There was no apparent reason for changing the medication, but care was taken to give the quinin doses during apyrexia and not within the last three hours before the expected attack. Up to October 5th there was hardly any change in the daily recurrence of temperature. The spleen became palpable and appeared sensitive on pressure; meanwhile no anomaly of heart, lungs, or kidneys. Quinin was then stopped, and fluid extract of ergot given in six, after five days, in five, after ten days, in four, daily doses of 10 minims each. On and after October 7th, no attack of fever; on the 10th the spleen could no longer be felt. Ergot was continued to November 15th, and Fowler's solution and syrup of the iodid of iron were given from October 15th to the end of the year.

CASE IV.—Mrs. M., thirty-one years old. In moderate health until the summer of 1890, though she lived in East 117th street, New York, a hot-bed of malaria even at the present time, until August when she moved to Brooklyn. The only exception to her average health consisted in neuralgic pains of uncertain duration, and at irregular intervals. Left hemicrania she had had for years, neuralgia of the left upper extremity during the summer; and for several weeks before she presented herself on November 24, 1890, neuralgia of the right lower extremity, posteriorly. This pain grew worse from slight pressure; deep pressure would diminish it. She had an extensive and loud systolic, a mild diastolic murmur, no enlargement of the heart, pale lips and conjunctivæ, and a small pulse of eighty. She had suffered from chills and fever since September; the tertian type had changed into the quotidian after a week; later she had two attacks a day. They would intermit now and then after heavy doses of medicine. During the previous fortnight she had taken 400 grains of quinin, and had almost daily attacks; she had a chill with a temperature of 104.4° F. in my office. Her spleen was 15 cm. long, 8 cm. wide, and sensitive over such of its surface as could be palpated. She was ordered to go to bed for at least a week, and to take 0.5 of calomel; at the same time a teaspoonful of Squibb's fluid extract of ergot four times a day in whisky and water. When after three days her chills continued, the dose was given six times a day, and no chill occurred after the fifth day until she presented herself on December 3d, nine days after her first call. Her spleen was 3 cm. shorter and less sensitive. She then was ordered 0 75 of sulphate of quinin once every fifth day in the forenoon, and the ergot was continued in the same doses. On Decem-

[1] Dr. E. R. Squibb, in a letter dated September 21st, has kindly informed me that it was first prepared by Professor Wm. Procter, Jr., of Philadelphia in 1857 ("Proc. Amer. Pharm. Asso. for 1857," p. 130, and 1859, p. 271), and by himself since 1859.

ber 7th she had a slight chill while still in bed in the morning. On December 10th, the ergot was reduced to 15 c.cm. a day, in four doses; on the 20th to 10 c.cm. On that day her spleen could still be felt slightly below the ribs. The quinin was continued to about the middle of January, the ergot another month afterward. At the same time, from December 20th to the end of January, she was given iodid of potassium, 5 grams, three times a day.

CASE V.—M. H., twenty-six years old. Was admitted November 11, 1897, and discharged December 6th. Was a moderate drinker and not venereal. Had no previous sickness. After a two-weeks' sojourn in the South in September he had one morning a chill which lasted one-half hour, and was followed by perspiration. Such attacks he had every other day for two, then every day for three weeks. Quinin was taken and the type of his fever became tertian again. Lately, while he was still taking quinin,—mostly, he said, when the chill came on and enough to affect his hearing,—the type of his fever became mixed, sometimes every day, sometimes every other day, with a few intervals of some days. On the 11th of November his temperature was 100.4° F. at noon; a chill came on at 2 P.M., with a temperature of 103.2° and 104.4° F., which sank gradually. His spleen was quite tender on pressure below the ribs, and up in the seventh intercostal space, and was about 13 or 14 cm. long, as revealed by percussion. Plasmodia were found in large numbers. Squibb's fluid extract was given in four daily doses of a teaspoonful (4 c.cm.) each. The highest rectal temperature of November 12th was 100.8° F. at 2 P.M., of the 13th, 99.4° F., of the 15th, 99.2° F., 16th, 99.8° F. No chills. Did not feel quite well on the 20th, and was given a few teaspoonfuls of sodium sulphate. Highest temperature 99.6° F. at 8 P.M. Because of indigestion, with coated tongue, took sulphate of magnesium on the 21st. Temperature 101.2° F., but no chills. Spleen smaller, less sensitive, plasmodia still found occasionally. Highest temperature on the 22nd, 101.8° F., on the 23rd, 102.2° F., on the 24th, 101.8° F., on the 25th, 100° F., on the 26th, 99.8° F. During all these days he never had abnormal temperatures like those he exhibited while under the uncontrolled influence of his malaria; but normal they were not. Evidently the rise extending over days was due to an additional, probably, gastric influence. About this time plasmodia disappeared from his blood. He remained under observation more than a week, and was then discharged.

CASE VI.—T. B., twenty-eight years. Admitted May 10th. Had had syphilis nine years before, gonorrhea several times; was otherwise healthy with the exception of slight colds; drank "some." His feet had been swollen a little for seven months. During the previous three months had had chills and sweats, off and on, he said. Took a great deal of quinin, almost daily, which helped him. Temperature on admission 101.4° F., pulse 118, respiration 28; pallor, anemia. Sibilant and sonorous breathing over both lungs, anteriorly, breathing diminished over base of left lung posteriorly, with subcrepitant râles and dulness. Liver flatness from sixth rib downward to below the costal border; the organ was felt nine centimeters below it in the parasternal line. Spleen extended from the seventh rib in the axillary line to the crest of the ilium and to within 2½ centimeters of the median line. No edema, no ascites; kidneys negative; axillary lymph bodies slightly enlarged. Plasmodia found pigmented, flagellated, segmented. Fluid extract of ergot 4 c.cm. four times a day on and after the 12th of May, preceded by a dose of calomel and sodium bicarbonate on the 10th. May 15th: no chill since; no diminution of size of spleen, which feels a little softer. May 23rd, was up and about all the week; no paroxysm, spleen softer, no flagellated and no segmented plasmodia. Had no paroxysm to the end of the month; at that time no plasmodia, and spleen was less tense and shorter by almost three centimeters.

These cases are selected almost at random from my records; a great many were never recorded, since my experience with the drug was no longer doubtful. In connection with the subject I may here state that my success with ergot in chronic and relapsing malaria encouraged me to try it in many cases of acute malarial infection. I am certain that many such cases will respond to the action of ergot, but in the average case less rapidly than to that of quinin. Indeed, these experiments were made for the sole purpose of observation.

CONCLUSIONS.

1. There are cases of chronic intermittent fevers with large tumefaction of the spleen, that after having resisted the action of quinin, arsenic, methylene blue, eucalyptus, and piperin are benefited by ergot.

2. When enlargement of the spleen is not old and not firmly established the contracting effect of ergot is noticed within a reasonable time.

3. The attacks will disappear before the diminution in the size of the spleen is very marked.

4. Though temperatures, after the employment of ergot, remain irregular and now and then somewhat elevated, chills, as a rule, are not noticed with this elevation.

5. Plasmodia do not seem to disappear from the blood so rapidly as they do after quinin, when the latter is effective. But even while some are still present, the attacks being more or less under control, the patient will feel better.

6. Complicating local pain requires additional treatment with ice, or cold douches, or heat; chronic hyperplasia demands iodid of potassium or iodid of iron. Digestive disorders may indicate, as they often do, when quinin is expected to act,

before the employment of ergot, an emetic, or a purgative, or stomachics.

7. An experience extending over forty years in which I have used ergot in many instances, justifies me in asserting at least this much: that there are many cases of chronic malaria, apparently intractable, that will get well with ergot.

8. There are cases, occasionally, in which the return of elevations of temperature after the successful use of ergot makes the combination of ergot and quinin, or ergot and arsenic advisable, though quinin and arsenic had not been successful previously.

9. Ergot, like quinin, probably by its sudden contracting effect on the spleen, and by the forcing of large quantities of plasmodia-laden blood into the circulation, is, in chronic malaria when hydremia and spleen tumor are excessive, capable of bringing on the very first attack of chills and fever.

10. Recent cases of malaria have got better, or were improved under the extensive use of ergot, but many resisted a long time; that is why acute cases should rather be treated with quinin.

Discussion.

Dr. Beverley Robinson of New York said: If we look back I think we must all be of the opinion that probably blood-vessels in the different organs are affected; they seem to have a notable effect upon the malarial condition and, I should imagine, through the diminution of the size of the spleen in old malarial cases. The probability is that quinin does have some contracting influence on the spleen itself in addition to any particular effect it may have upon the blood. With that I can understand that there is a rational view with regard to the action of ergot in its effect on the size of the spleen, and when the spleen comes to be contracted the malarial condition is fatally affected.

I would like to speak of something that I am extremely interested in, and hope some of the gentlemen present will be good enough to give their opinion. In a paper before the New York Academy of Medicine I called attention to the use of the tincture of bark in repeated doses and spoke of cases in which it had been notably useful. The cases were pretty closely observed in hospital wards and in my practice outside. If any of you have not read Huxham's original work on the treatment of fevers, and his remarks with reference to the treatment of malarial fever, I think you will be very much interested. It was published more than a hundred years ago and he gives the formula now used. He attributes a certain amount of merit to snakeroot. I believe we are getting away from facts which are of very great value. We are disposed to believe a little too much in using our alkaloids, because they are useful and are so easily administered. The bark itself is of very great benefit. I think there is a rational basis of belief that the bark itself will be of use in removing the poison of malaria. The bark must be given in many of these instances if one wishes to secure the best effects. I would refer to one preparation by a firm in the West, Parke, Davis, & Co. Compound fluid extract of cinchona is nothing more than the compound tincture of cinchona with five times its strength, so that if one gives 5 or 10 minims of the compound cinchona he is giving five times the strength of the tincture. I have found it a very useful way of giving the bark and have obtained very good effects from it.

Dr. R. G. Curtin of Philadelphia said that the treatment of malaria by ergot would be a valuable addition to any specific treatment, by not only helping to keep down the size of the liver and spleen during the acute attack, but also by preventing the subsequent chronic enlargement of these organs.

Dr. Judson Daland of Philadelphia said: I have listened with great pleasure and profit to the remarks made by Dr. Jacobi in reference to the action of ergot in malaria, and I was especially interested in the observation regarding the influence of the drug on the spleen. In regard to those cases of malaria uninfluenced by quinin, so far as Philadelphia is concerned, we have very few cases that do not yield to the action of this drug. Along the Gulf States, more particularly in Louisiana, I am informed, a number of cases have occurred in which quinin has not exerted its usual beneficial effect.

One year ago while in Tiflis, at the Civil Hospital, Professor Gurko informed me that frequently they receive cases of malaria from the neighborhood of Batoum, on the Black Sea, which are influenced by large doses of the bichlorid of quinin administered by the mouth and hypodermatically. He stated that in the few months preceding he had treated in this way six cases. The cases had been accurately studied, the parasite had been pictured, and these pictures were shown me, and of the six cases five had resulted fatally. He also stated that many of these patients present symptoms of typhoid fever before the parasite is found in the blood, but other examinations have showed the affection to be malaria and not typhoid fever.

The use of quinin in malaria as we see it in Philadelphia sometimes fails to give results in cases unquestionably malarial, for several reasons. I recollect two such cases in the Philadelphia Hospital where the patients had malaria as demonstrated by the presence of the plasmodium in the blood. Quinin was given in sufficient quantity, but most of it was recovered in the stool, and I have no doubt that in many cases of malaria the quinin is either insufficient primarily, or the pills are old and hard and only partially dissolved, or it is in capsules that are old and pass the pylorus and probably escape in the feces without the organism being impressed with this salt of cinchona. With the detection of the plasmodium of malaria, the number of cases of malaria in Philadelphia has rapidly decreased, until at the present time, except those cases coming from the Eastern Shore of Maryland and other malarial points, the disease is practically a rare one, and on an aver-

age in not one case in ten that are examined where the diagnosis of malaria has been made has it been verified by an examination of the blood.

Reference was made to the time of giving the drug, which is a matter of some importance, and it would seem as though, from what we now know of the disease, that the plasmodium is most exposed to the antidotal action of the quinin at the time when it has become the matured malarial body, floating free in the blood. It is quite evident that when the plasmodium is within the red blood-corpuscles quinin in solution in the plasma will not be able to exert its antiperiodic effect, but when the body breaks through the envelope of the red cell and enters the circulation quinin promptly destroys the parasite.

I would like to call attention to one case which unquestionably would have ranked a few years ago as a case of malaria. The patient had intermittent fever, occurring daily with the customary symptoms of the paroxysm. Examinations of the blood, urine, and viscera gave negative results. Examinations were repeated. The urine showed no change. The autopsy showed suppurative kidney with calculi impacted in the ureter. It would seem as though these calculi temporarily occluded the passage of urine from the diseased kidney, but when the accumulation of urine became considerable, dilatation of the ureter took place, and partial escape of the contents occurred. The urine that upon examination gave negative results was probably secreted from the healthy kidney, while there was temporary obstruction of the left ureter. No distinct tumor could be found, although while examination was interfered with by the obesity of the patient, swelling was detected in the left renal region.

Regarding the action of ergot upon the essential poison of malaria, I doubt very much whether it has this effect. I personally have not had much experience in the use of this drug, for the reason just stated. As a rule, the disease as presented in Philadelphia yields to quinin. The poison that produces the paroxysm seems to be the result of the gradual maturing of the parasite of malaria, and at the moment of its maturity there seems to be thrown into the blood a chemical poison, this seeming to initiate the paroxysm, and I doubt whether ergot has any special influence over this low form of animal life.

Dr. Didama of Syracuse, N. Y., said: I live in a region which used to be swampy, and chills and fever were prevalent. Nearly forty years ago physicians treated the cases there by first giving something, such as calomel, to prepare the system to take the antidote of the poison. We knew nothing about bacteriology at that time. I could not see why we should not give an antidote at once, and so at that time I commenced giving that which I have been giving ever since. There was a tendency for the chills and fever to return in about seven or fourteen days. Then in order to prevent that return I thought I would repeat the medicine about every six or seven days, so I would give the patient ten or eleven powders, each one containing 4 to 5 or 6 grains of quinin with piperin and some sulphate of iron. I have never varied the size of the dose from that day to this. The patients took the powders without any reference to what time of day the chill occurred. They took one in the morning and one in the afternoon or toward evening. A few of these powders were put up in blue papers, and the patient was to take one of these every Sunday morning for three or four Sundays. The men kept at work as usual, but there was no return of the disease that season. The next season they might have it again, and it was cured in the same way. I have had from 200 to 250 cases a year. Patients in Michigan took the same medicine with the same result. There were some cases which I did not see early enough. In those cases of chronic malarial poison with enlarged spleen this treatment does not act as well, and I am glad that Dr. Jacobi has told us what he has about the ergot in eliminating the poison from the spleen.

Dr. Jacobi, in closing the discussion, said: There is no doubt that there are cases of malaria which do resist quinin, as there are cases that do resist arsenic, or quinin and arsenic together. I have seen them. If any man says he has not seen them (a great clinician whom I much admire rebukes those who do not succeed with quinin in every case), that is his luck and not mine. The spleen, of which we know almost nothing as yet, has certainly a great influence in harboring germs and in being the cause of the relapses not only in malaria, but in other diseases. I remind you of what we can all see in typhoid fever. I know that in a case of typhoid fever in which on the sixteenth or seventeenth day the spleen does not diminish in size there will be a relapse, or rather a continuance of the illness. In those cases in which the spleen diminishes in size about the sixteenth or seventeenth day, one is fairly certain that with the usual care there will be no relapse. That is one of the instances of which I can feel tolerably sure as a matter of experience, which is, that the spleen certainly has a great deal to do with the relapses of typhoid fever. So in malaria; if I succeed in reducing the size of the spleen within a reasonable time I feel sure that the malaria is under control, but in fever districts in the South as in the North, in the swamps, there are cases that will not easily get well. There are also those very obstinate cases in which the spleen grows very slowly for weeks and months, until finally cachexia is the first, and the "chill and fever" only the second, symptom. These cases are very apt to resist the influence of quinin. The practice Dr. Didama speaks of, of giving calomel before giving quinin, and getting the stomach in good order, is a very good one, mainly in these old cases. There are those in which quinin will not act until the stomach is put in good condition for absorption, by a purgative or otherwise; sometimes by an emetic or irrigation of the stomach, always by stomachics.

Regarding the preparations that I have used, I can say that I have not given a single sugar-coated pill for thirty years. I seldom prescribe drugs even

in capsules, because I know capsules may pass through the intestinal tract. I generally use powders in preference to anything else because I feel tolerably sure the quinin will then act. I order solutions only for those who do not mind the taste.

To-day I simply state to you my observations made during forty years or more, that there are cases of malaria which, after not getting well with quinin or with arsenic, do gradually get well with ergot. Now, there is no reasoning against that. If you always cure your patients with quinin only so much the better for you. I did not always succeed. In my failures I often succeeded with ergot. If some one does not see why that should be so I cannot to-day disperse his doubts. It is not the first time nor the last that empiric facts have collided with our insufficient information, and that theoretic reasons would come limping behind actual observation. I have tried to suggest the way in which ergot may prove effective in malaria; maybe a better interpretation of its action may be found. I believe I am on perfectly safe ground when I display my clinical observations, which, as I said, extend over forty years.

THE USE OF OBSTETRIC FORCEPS WITH REPORT OF TWO CASES OF INVERSION OF THE UTERUS.[1]

By J. F. COLE, M.D.,
OF OELWEIN, IOWA.

Probably no one subject is of greater interest to the general practitioner than that of how to handle difficult and tedious cases of confinement to the best interests of his patient. Not all physicians are adapted to this art; due to the fact that some do not like the work, and others lack confidence in their own ability. Many physicians abuse the use of forceps by applying them when not indicated, and producing serious damage to the mother as well as to the child. To properly understand the use of the instruments one must make a careful study of the different presentations of the child, as well as the peculiarities of the patient, such as stenosis of the cervix and deformity of the pelvis, abnormally developed fetus, etc. In normal labors with a roomy pelvis and a normal fetus, we do not need the assistance of forceps but do better by letting Nature take its course with occasional manual aid such as support of the perineum, slight pressure over the uterus, etc. But the question pregnant with vital interest to all practitioners is how to handle abnormal cases. This is a question of great importance, but how often do our authors neglect to give us a complete detail of how and when to act, and pass the subject almost unnoticed, especially as to its main technic! How many of our college graduates are there who do not know how to use the forceps correctly? How many there are who do not look after the sanitary condition of the lying-in-room, or the cleanliness of the bed and person of their patient, or in fact of their own personal cleanliness!

Now what are the indications for the use of forceps in confinement? (1) A small or irregular-shaped pelvis; (2) a large child and an abnormal presentation; (3) an alarming hemorrhage; (4) signs of failing strength or exhaustion; (5) convulsions; (6) when the presenting part becomes fast in the pelvis and labor pains are ineffectual; (7) when the interest of the mother and child requires a speedy delivery. All these propositions are, however, subject to the limitation that in the selection of the mode of delivery choice should be made especially looking to the maternal safety. Fortunately in the majority of the cases the interest of the child and mother are identical.

In preparing for the use of instruments it is always best to place the patient crossways of the bed, to elevate the head slightly and have the hips well over the edge of the bed, to wrap the limbs in a clean sheet or towels, then have a capable assistant give an anesthetic (chloroform preferable), while you carefully cleanse your hands and prepare your forceps. When the patient is fully under the anesthetic dip your forceps in hot water to remove the chill of the steel and anoint the blades with antiseptic ointment, and having determined the location of the head, apply your forceps so that they will catch it laterally. The blades should be applied by introducing the left blade first, allowing the fingers of the right hand to act as a guide to see that the walls of the uterus are not caught between the forceps and the head of the fetus, and also that the forceps are properly adjusted to the head. Then introduce the right blade, guided by the fingers of the left hand and when properly in position the two blades are easily locked. When the forceps are properly adjusted and locked the next step is to apply traction, which is best done by placing the right hand on the handle of the forceps palm downward, and grasping them by means of a finger on each side of the handle, and the left hand underneath, palm upward. It is advantageous to introduce the fingers of the left hand into the vagina occasionally to determine the position of the forceps, the location of the head of the fetus, and to estimate the amount of pressure on the child's head during traction. Steady traction is always preferable to the pendulum or rotary motion and especially is this true when the rotation of the head is incomplete. Pressure by a skilful assistant on the abdominal walls during traction is here, as in other obstetrical

[1] Read at the Forty-seventh Annual Meeting of the Iowa State Medical Society, held at Des Moines, Iowa, May 18, 19, and 20, 1898.

operations, an adjuvant of great value. Traction should not be too prolonged and when not made in unison with the pains they should not exceed two minutes in duration. The head should then be allowed to recede, for haste in delivery exposes the patient to danger of laceration and post-partum hemorrhage.

The alternate descent and recession of the head afford the best means of softening the external parts and overcoming rigidity; and as the head advances time should be given for the uterus to contract upon its contents, for when the pains are deficient the contractions, after too sudden emptying of the uterus, are apt to be improper or of short duration. Traction should at first be made downward until the head has descended well below the symphysis pubis; then horizontally until the occiput appears at the vulva. If in doubt as to the direction of traction hold the handles loosely in the hand during a pain to serve as an index of the proper time for traction. If rotation has not previously taken place you can aid it with the forceps, but it usually takes place as the head descends. When the parietal bosses are in the act of passing the vulva, traction should no longer be made. The operator should now stand to one side of the patient with forceps in one hand, and the other pressing against the perineum. Then during intervals of pain, by alternately sinking and raising the handles, the perineum and vulva can gradually be dilated. So soon as the convexity of the perineum is marked and the parietal bosses press on the commissure, it is best to sink the handles during a pain so as to flex the head to its greatest extent and cause if possible the vertex to present. When the vulva is sufficiently dilated raise the handles toward the abdomen, complete the extrusion of the head and complete the delivery. Some authors advise the removal of the forceps before the head is delivered and as soon as you can grasp the chin with the index-finger introduced in the rectum, but I prefer to leave the forceps adjusted until delivery of the head is completed, and find great advantage by placing two fingers over the forceps and under the symphysis pubis as a fulcrum around which the blades can be safely rotated.

I am not much of a believer in the high application of the forceps when the head at the brim is yet really movable, but would in these cases recommend version because it is more easily done and a much safer procedure, yet there are cases where this cannot be done. In these cases I would advise the forceps of M. Tarnier. In the high operation the finger should always guide the blades between the cervix and the child's head with greatest care, so that if possible, the head may be seized in the transverse diameter, instead of applying the forceps regardless of the position of the child's head. As a rule it will be found under the conditions mentioned that the head has been seized obliquely, *viz.*, with the posterior blade over the parietal prominence and the anterior blade near the coronal suture. In this case you cannot closely approximate the handles, and you should only use enough compressive force to keep the forceps from slipping. To adjust the lock often requires considerable patience and in many cases a great deal of pressure, even when the forceps have been applied by strictest rules of the art. It will not infrequently be found that the upper border of the anterior blade and the lower border of the posterior blade will project beyond the scalp-tissue and unless managed with great care the exposed edges are liable, during extraction, to cut deeply into the tissues of the parturient canal. When the os is only partially dilated, the forceps should be used, not as extraction instruments, but simply to bring the head down against the cervix to expedite dilatation. In this great care should be taken during a pain to see that there is not too much tension upon the firm and unyielding os externum, and thus avoid a troublesome laceration of the cervix. When dilatation is complete and the head is brought down into the outlet of the pelvis the mechanism is the same as in other cases.

In cases of occipitoposterior position it is always best to refrain from using forceps as it prevents rotation, yet there are cases in which it is justifiable, *viz.*, when speedy delivery is required for the welfare of mother or child. In these cases it is best to apply forceps to the sides of the child's head and to imitate the mechanism of normal labor in posterior positions. If the sagittal suture occupies an oblique diameter the forceps should be applied in the opposite oblique diameter, as the occiput should be rotated into the hollow of the sacrum. Then the lines of the traction are the same as in the vertex, only that the face instead of the occiput rotates under the arch of the symphysis pubis. In face presentations when the presenting part is deep down in the pelvis and the chin has rotated to the front, application of the forceps is easy and does not differ materially from the procedure in presentations of the vertex. Traction should then be made horizontally until the chin has been brought well under the symphysis pubis, when the handles should be raised to lift the cranial vault over the perineum and thus prevent serious laceration. In the oblique mentoposterior positions, Speigelberg recommends the introduction of the posterior blade first or the one corresponding to the chin, as in adjusting the second blade and locking the forceps, spontaneous rotation nearly always

takes place. In deep transverse positions defer the use of forceps as long as possible as a tardy rotation of the chin to the front is a physiologic peculiarity in face presentations. In all these cases the forceps should be applied obliquely with the concavity of the forceps directed toward the chin. Then try to rotate the chin to the front, but if you fail to rotate the chin to the front, traction should not be made, but if you succeed in rotating the chin to the front the forceps should be unlocked and readjusted to the lateral surface of the head to prevent pressure being made upon the neck and throat.

In high transverse positions forceps should not be used as rotation is not then permissible and the blades applied to the neck and thorax on one side and upon the cranium on the other, separates the handles so far that the pressure necessary to keep the blades from slipping is so great that you cannot deliver the child without causing death or great injury. The choice in such cases requiring speedy delivery lies between craniotomy and version, the choice of which depends upon the conditions existing in each particular case.

In breech presentations where no alarming symptoms exist for mother or child, the attitude of the obstetrician should be one of watchful observation, for as a rule the results to the child are far more favorable when Nature does the work unaided, yet the physician should always be on the alert to meet successfully by interference any cause which may produce a delay in breech presentations. The delivery in breech presentations consists of three stages: delivery of trunk and body to shoulders; delivery of arms; delivery of head. The first stage extraction of feet and breech should be made slowly, giving time for contraction of the uterus. The second and third stages should be finished as rapidly as possible and much the same rules must be followed as in vertex presentation, using instruments only when absolutely necessary.

This, in brief, is the mode of using forceps in labor. But much depends upon the cleanliness of the patient's bed and antiseptic precautions of the surgeon as to the recovery of the patient and after-health of the mother. Always wash the parts with an antiseptic solution before applying the forceps; thoroughly cleanse your hands and arms; prevent any infection from your clothes by wearing a sterilized gown; wrap the patient's limbs in wool and cover with clean sheets to prevent infection, and also to keep the extremities warm; have the patient placed crossways of the bed with the hips well over the edge of the bed, with a clean sheet under and over them. Two assistants, one on each side to hold the limbs, and a competent person to give chloroform and you are in readiness to proceed to apply forceps and deliver the child. In a case thus handled and with these precautions the use of instruments is attended by little or no danger to mother or child, in fact it is not so dangerous as to wait until the patient is exhausted or until injury has taken place to soft parts by too long continued pressure caused by the presenting part of the fetus. Hence I should recommend the use of forceps whenever the presenting part becomes fixed and the pains no longer have any effect upon forcing the fetus through the parturient canal or where the secretion of the vagina has ceased and the parts become dry and feverish, when there is no hemorrhage, convulsions, or marked exhaustion of the mother. If we will only follow these precautions, forceps will not be looked upon with fear but will be hailed as a welcome boon to women in labor.

In conclusion allow me to report two cases of inversion of the uterus. This complication is of very rare occurrence, therefore I deem it of sufficient interest to the obstetrician and practitioner to report briefly the two cases which it has been my lot to see. It is one of the most serious accidents that can befall a woman in labor. The inversion may be complete or incomplete; may occur at the third stage of labor or a few hours after labor. Of the cases I wish to report, one was in my own practice and the other in that of a midwife. The production of inversion may be favored by a large relaxed uterus, the result of over distention, of rapid delivery, or hemorrhage. The immediate cause may come from pressure exerted from above or traction from below. It may come from straining, especially in the kneeling position, or from attempts to expel the placenta before uterine contractions have been secured. It may come from a short or coiled cord during labor, from too much traction on the cord after the fetus is born, or from the weight of the placenta itself, and especially is this true when the placenta is attached to the fundus instead of the lateral wall of the uterus. In incomplete inversion you have the saucer or cup-like shape of the fundus. In complete the fundus comes down into the vagina and may protrude through the vulva, the cervix being inverted to its vaginal attachments. The symptoms are shock, hemorrhage, pain, restlessness, pallor of face, a quick pulse, syncope, etc. Shock is marked by small pulse, cold extremities, vomiting, and sunken features. Spontaneous reductions of both incomplete and complete inversion have been reported, but are not very common. The diagnosis is easy for the condition can only be mistaken for a uterine polypus. Prognosis depends upon the promptness of the operator in returning the fundus

to its normal position. Yet, according to the statistics of Crosse, one-third die either at once or within a month of the accident. Treatment consists of pressing the fundus up with the closed fist, counter pressure being made with the disengaged hand upon the upper border of the funnel-shaped depression. If the placenta is detached to any great extent it should be removed before attempt is made to replace the uterus, but if adherent, lose no time, but push the placenta and fundus back together.

CASE I.—After several years of practice, I saw my first case of inversion of the uterus about one year ago. I was hurriedly called to see Mrs. L., primipara, aged twenty-two years, some nine miles in the country. She had been in labor thirty-six hours, and was being attended by a midwife. When I arrived at the house, members of the family and attendants ran out, saying the child was born but the lady was dying. I went in, and found her pallid, nearly pulseless, and suffering from a frightful uterine hemorrhage. An old midwife standing by said, "You must hurry up, doctor, this lady's insides are coming out." I pulled off my coat, rolled up my sleeves, and not waiting to use any antiseptic, made an examination. I found the uterus already protruding from the vulva. Here I was, without any assistance (of any consequence), and my first case of this kind. I saw that I had to act and act quickly, so I placed my left hand over the abdomen, and with my right hand against the fundus of the uterus I began making the uterus retrace the same steps it had taken to reach the condition in which I found it. I finally got the fundus replaced to its normal position, and with one hand in the uterus, and using Crede's method with the other over the abdomen, I finally got a firm contraction of the uterus. While doing this I had the patient given whisky and ergot freely, and as soon as I got contraction I gave her ergotin and strychnin hypodermatically. The patient made an uninterrupted recovery. I used copious injections of hot water and bichlorid solution, gave tonics, and a generous diet. In this case the midwife had killed the child, and had pulled on the cord until she tore it loose from the placenta, and said that the reason the lady was so sick was that she had no afterbirth.

CASE II.—Mrs. M., multipara, aged twenty-seven, was delivered of a hydrocephalic fetus by instruments. The case progressed nicely until the body of the child was passing through the vulva, when a severe hemorrhage occurred. I delivered the child as soon as possible and cut the cord, which was only eight inches long. By this time the patient was pallid, pulseless, cold, and, in fact, in a state of complete collapse. I had my assistant give whisky, strychnin, and ergot hypodermatically at once, and when I attempted to get contraction of the uterus by manual aid I found to my surprise a case of inversion of the uterus, with the placenta well loosened. This I hurriedly removed, and at once proceeded to replace the fundus of the uterus to its normal position by means of pressing the fingers of one hand against the fundus uteri and the other over the hypogastric region of the abdomen to prevent the rupture of any of the parts from the force being applied from below. I was able to quickly replace the fundus, and allowed one hand to remain in the uterus a few seconds, producing contraction by Crede's method, and by the hand in the uterus. When the contractions were sufficient I withdrew my hand slowly to prevent a recurrence of the trouble. The uterus was then washed out with a hot bichlorid solution 1–3000, followed by hot sterilized water. The patient was given a dram of ergot every four hours, tonics, whisky, and well-regulated diet. She made a complete recovery in four weeks, and there is no lesion to mark the occurrence of the accident.

In my first case the fundus was replaced without any anesthetics or assistance (of any consequence); in the last chloroform was used. But when the patient is wholly unconscious and nearly lifeless an anesthetic is not so essential as is speedy work of replacement. Yet, while I was successful in these two cases, I have no desire to see another. The after-treatment should be much the same as in atony of the uterus in post-partum hemorrhage. By carefully but firmly indenting the fundus with one hand and making counter-pressure with the other over the ring-like neck above, carrying the hand up through the os into the normal cavity of the uterus, not only can the reposition of the fundus be secured but it can be maintained.

ADDRESS.

THE GENERAL PRACTITIONER.[1]

BY JAMES TYSON, M.D.,
OF PHILADELPHIA;
PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA, ETC.

IT has often been said of the essayist or lecturer, "Given his subject and his task is half accomplished." I may be said to be in that fortunate position, because you have been good enough to select my subject for me. On the other hand, this method implies difficulties which are peculiar to it. It may be that with the subject set, a special mode of treatment is expected which the speaker may not hit upon. I may disappoint you in this respect, and should I do so, it will, unfortunately, be too late to mend matters except so far as my extreme regret can atone for any shortcomings.

At the outset we are met with the question, "What constitutes a general practitioner?" Clearly in the broadest sense, he is one who shrinks from no service which belongs to his art. He is at once physician, surgeon, obstetrician, gynecologist, ophthalmologist, in a word, anything which has received a title in the differentiation of professional work. Yet it is evident that it is not pos-

[1] Delivered at the Eightieth Anniversary of the Founding of the Gloucester County Medical Society, September 15, 1898.

sible for any one man to fulfil the requirements of all these offices as demanded by modern medical science and art. Very different was it a hundred years ago. Then one man could do quite all that could be expected of him. Even at that date the larger cities contained men who were especially distinguished for operative skill who did little else but surgery. Such men in their day were Sir Astley Cooper and Sir Benjamin Brodie. Yet the entire field of medicine was reasonably considered as within the province of one man. It is evident, therefore, that some latitude must be allowed in defining the duties of a general practitioner of to-day. Casting about us for the field actually filled by him, we find he is one who practises first of all medicine in its broadest sense, including not only the diseases of children, but also skin diseases. He practises midwifery. In surgery he, for the most part, limits himself to minor surgery, while he is repeatedly called upon to prescribe for the simpler affections of the eye and ear. The more complicated technic which modern medicine has imposed upon the proper treatment of diseases of the nose and throat, demands vastly more time and trouble than the older treatment of these affections, and yet the general practitioner cannot escape it if he would retain his practice, though in the cities this department is largely becoming an exclusive province. It is more than likely, however, that time will simplify the treatment demanded by these diseases. From the surgery possible to the general practitioner, orthopedics is practically excluded, while genito-urinary affections necessarily fall within his province. As intimated, in the cities the major operations of general surgery are practically withdrawn from the field, but in the country this cannot be so, else must life often be sacrificed. The same is true of major surgical operations now placed in the department of gynecology. Hence the term "general practitioner" must include more in the country than it does in the city. The general practitioner of the city is more limited in his work, as much by the will of the patient as by his own selection.

To sum up, then, the general practitioner of the present day is, in point of fact, a man who practises all the departments of medicine as distinguished from surgery; who practises midwifery, surgery, and gynecology, except the major operations demanded by it and by surgery, and who treats also the minor affections of the eye and ear. While this is practically true of the general practitioner of the city, the field must be extended in the country to include all operations, delay in which is dangerous to life. And it is the general practitioner in the country, I take it, you have in mind when you ask me to treat the subject. It is in the country only, in fact, that the general practitioner in the truest sense can be met, so that in a word the general practitioner is the country practitioner. As such, I am inclined to think, too, that the correction of the simple defects in refraction, and the prescription of glasses should fall to his lot. I see no reason, at least, why he should be excluded from this source of revenue. Thus it will be seen that, view it as we may, the field of the general practitioner is a broad one.

Having described the field of the general practitioner, we naturally come to consider his qualifications, and it may be that I will surprise you somewhat in what I shall include among these. A moment's reversion, however, to the numerous duties I have assigned him will make it evident that his attainments to be commensurate, should be correspondingly broad. I have more in mind, too, than that his attainments shall simply fit him for these duties, remembering that the object of life is something more than the simple fulfilment of duty, and that health, happiness, and enjoyment are a heritage to which the physician is as much entitled as other men. To this end I consider that the general practitioner should have the broadest preliminary culture attainable. Much more than the specialist would I clothe him with a broad general culture. I would have him college-bred or the equivalent of college-bred. I would have him able to at least *read* Latin, French, and German, while if he chose to include in his preliminary education the now much-despised Greek, I should regard him as no less fitted to fill the important rôle I have set for him. I would have him well drilled in physics no less than in chemistry, for no one is qualified to understand the problems of physical diagnosis, as set by diseases of the circulatory and respiratory systems without a thorough knowledge of acoustics and hydrostatics, while with such knowledge their understanding is comparatively easy. Equally too, would I have him versed in the natural sciences—botany, mineralogy, comparative anatomy, and zoology—a biologist in the broadest sense of the term; for through such attainments I expect to add to his pleasure as well as to his usefulness, to make his otherwise lonely drives and walks holiday excursions pleasurable and profitable. I would have him well-read in the standard literature of his own and foreign languages, the latter not, of course, in the original, but in the excellent translations which abound; for I acknowledge that the general practitioner has a limit to his capacity for attaining and remembering, but I insist the more on his getting as much knowledge as possible of this kind before entering on practice because while he still may have time to enjoy it after he enters on professional life, he may not have time to acquire it. In a word I would have him equipped with all that will make him accomplished, ready, and versatile, with a view to enhancing his own pleasure and enjoyment, that he may appear the equal as well as the superior of those with whom he mingles socially and professionally. He should be at least the intellectual equal of the most intellectual of his community, the man to whom young and old alike will go for information on subjects on which they are in doubt, as well as for treatment of their physical ills.

On the details of his professional education I need not dwell long, for it goes without saying that he should have the best his money can obtain. Nay more, if he has not enough money to obtain the best let him defer it until he can raise more, if money be the measure of its quality. For a cheap medical education is like a cheap garment; it may serve its purpose for a short time but it soon needs repairs, the ultimate cost of which will far exceed that of a good one, while it is an ever-growing disappointment to its possessor. No medical man needs a broad and

thorough medical training so much as the general practitioner, for no one has such varied demands upon him, no one is so constantly thrown on his own resources. To this end hospital residence in a general hospital for a year at least after graduation should be secured when possible. He should be familiar with the use of instruments of precision such as the microscope, ophthalmoscope, apparatus for the examination of the blood and the testing of ths urine, as well as with the stethoscope and laryngoscope.

We are now ready to locate the general practitioner. Equipped as he has been, he may locate in any community he chooses without fear that he will appear at a disadvantage compared with other citizens of the same town. We will not follow him in the selection of his home, for this is a personality with which we have no concern. His consulting-room should, however, be well appointed with all that will facilitate the examination of patients and the study of disease. A small apartment, or in the absence of this, a corner of this room should be fitted up as a laboratory with the instruments of research and accurate investigation referred to, as well as necessary reagents for such chemical and chemico-microscopical work as he will be called upon to do. Such an outfit is neither large nor expensive, and it is indispensable. A man is much more apt to study a case thoroughly if he is provided with suitable appliances. These should be kept in perfect order, and so placed that no time is lost in getting hold of them for use.

As indispensable as anything in the outfit of the general practitioner and more useful than a horse and buggy, in the days of the bicycle at least, is a neat, bright, quick-witted, intelligent wife. No one but he who has one knows what a treasure such a wife is. Simple beauty of person is something to which one soon grows accustomed. The homely adage that "beauty is only skin deep" is full of meaning, and the qualities referred to make the possessor dearer with every year that elapses. There is nothing that such a wife cannot do. Besides being a cheerful helpmate and loving companion, she will keep our general practitioner's books and help him with his cases, which he will talk over with her, but which she will regard as sacredly confidential. Nay more, she can learn to test urine and even to use the microscope and otherwise help even more than a qualified assistant, because she is actuated by love and a common interest, attributes scarcely to be expected in a paid assistant. On the other hand, nothing is such a drawback to the general practitioner, the man whose work calls him into so many channels, as a careless, slouchy, novel-reading wife. I have known more than one man's life blighted because he was handicapped by such a companion. Nor need he long defer his marriage if she is of the right kind. To marry on nothing is most ill-advised, and I subscribe heartily to the old Greek maxim, "How thrice is he unhappy who marries poor." But the physician who waits until ample means are accumulated before he marries loses the best part of married life, the part to which he will look back with greatest satisfaction in after years of comparative ease and disembarrassment. As soon, then, as he begins to see his way clear to reasonable success, he should marry a sensible, well-educated woman, a little younger than himself.

We now have our general practitioner well educated, thoroughly trained, and well equipped. How shall he attain what is called success? We will not stop to discuss what constitutes success, except to say that it consists neither in wealth nor in power, nor even in health, but in a certain proportion of each of these, fortified by a consciousness of rectitude and the determination to be content with the results of efforts as well directed as he knows how. Then as to what constitutes well-directed effort, no effort of the physician is well directed unless governed by the spirit of the Hippocratic oath; that he will do his best for his patient and sacredly guard the confidences placed in him. We will not ask him to take the oath for we are of a profession that is above oaths, holding that an obligation is as binding without it as with it and that it does not add to the force of such obligation.

We may, however, continue our subject by pointing out some of the methods which judgment and experience have shown to be well directed. First, the general practitioner should establish an office or consulting hour at home and punctiliously maintain it. The office hour is often too much ignored by the general practitioner, and especially by the country practitioner, to whom my mind constantly reverts as the true type of the general practitioner. The most important requirement of an office hour is that it shall be kept. It does not much matter at what time of day it is, so that it is rigidly observed. It is soon found out and greatly appreciated. Doubtless in the country, the evening is more convenient to the patient, but it is important for the success of the office hour that the physician should be fresh and well rested, else the duties of the hour become irksome and are unspiritedly and carelessly performed. Hence the morning is, on the whole, the most suitable—say until nine o'clock or half-past—for your general practitioner must be an early riser as his patients are also likely to be. Then, after his office hours he will still have a long day before him, all of which he will need in order to fill the important and busy rôle we have mapped out for him.

More time still will be gained by a systematic arrangement of work. The busier one is the more important this is. I am certain that at times the general practitioner is too indifferent to this and loses much time in consequence. With an office hour terminating at 9, or at the latest 9.30, he should start promptly on his tour of visits, giving enough time, but not more than enough to each patient. Many practitioners make their visits too long and not only thus lose time, but diminish the respect of their patients for them. Every physician should consider his time valuable, as it really is, because there is always more to do in various directions connected with his present and future usefulness than can be accomplished in a day. He need not, indeed should not, indicate by his manner that he is in a hurry; this is harmful to his interests. On the other hand, he should not loiter, especially should not gossip; for however entertaining or pleasing this may be to the patient, it will not increase the respect of the

latter for him, and may even jeopardize the estimation of his counsel. One of the best pieces of advice I ever had given to me before I began practice, was that of a very dear friend, a lady, who said to me one day, "Doctor, when you begin to practise, do not make your visits too long." She had evidently suffered from the long-drawn-out visits of her doctor. She was a great contrast to another patient, also a woman, of a busy friend of mine, to whom she said when he manifested some uneasiness at *her* prolonged call, "Why, Doctor, you seem to want to hurry me off. My own doctor keeps six horses and he stays an hour at each visit." Further comment is unnecessary.

With work well arranged and no time lost on needlessly prolonged visits, a surprising amount of time will be found remaining over after the daily round is made. The leisure thus obtained should be spent first in clearing up doubtful points in cases by the study of well-selected text-books and current medical literature—his journals. It is surprising how often the attentive reader of journals finds in their pages cases corresponding to his own which will help him to clear them up and often to treat them. On this account the general practitioner should subscribe to at least one first-class weekly medical journal, still better for two published in different cities; though it will be more profitable to read one such journal well than to have two and read neither. It will do him no harm also to subscribe for a journal with a more general scientific purpose, such as *Nature* or *The Popular Science Monthly*. This he may have to skim over but it will still help to keep him interested in natural science. His journals are the means by which he is to be kept in touch with the latest additions to his art and science. One or two magazines devoted to general literature should be found on his table, to say nothing of a good modern newspaper, of which a good abstract of daily news and good editorials should be a feature; for I have already said that our general practitioner will have no time to waste on diffuse and voluminous accounts of events which are contradicted the next day. Abstracts and first-class editorials are what he wants, the latter to be read in the evening if time permits, the former for a few minutes in the morning.

To proceed with our methods, next, or perhaps first, he should make a brief note of at least the important cases seen during the day as far as they may require it. I believe there is no single piece of systematic work which is as useful to the general practitioner as note taking of this kind. It may be said that this is impossible, but it is not. I do not refer to notes of office cases for this is easy. Practice in such noting soon leads to a brevity which greatly facilitates it, and here the loving wife may lend a helping hand, to be replaced by the stenographer as business grows and family cares demand the wife's attention elsewhere. Fortunate is the physician who happens to be a stenographer himself. Much time and space are saved by this accomplishment. One of the most interesting and valuable lectures I ever listened to was by a busy physician who had adopted the method of note taking recommended, not by shorthand, but in the ordinary way. The address was based entirely on notes of cases in private practice taken from the daily note-book to which a few minutes each evening were devoted. Whether such notes are employed for any future purpose or not, the practice is invaluable, leading to systematic arrangement of facts and thought, and developing accuracy of observation which reacts again and again to the direct advantage and usefulness of the one who employs it.

Nor should he omit to spend a few minutes as opportunity offers on current secular literature. A volume should always be at hand which can be taken up when a few minutes of leisure are present. Some one of the numerous inexpensive critical reviews treating of current literature and containing abstracts of the books of the month should be one of the magazines referred to as useful. By means of this he can keep himself informed of what is going on in literature and select the volume to which he is to devote the few odd moments which are always turning up. A volume of poems from an author cast according to the mold of his own taste may be such a volume or be one of two or three which may be at hand to be picked up at such times.

Emphatically our general practitioner should be a member of the local medical society and should attend all its meetings, at first as a listener. For before anything else he wants to win the regard of his fellow practitioners, and he is almost sure to obtain the opposite if he is too ready to seize every opportunity to ventilate his views, which are apt to be regarded as fresh and crude even if they are not. Gradually, as he becomes known by his regular attendance and close attention, he may rise to ask a question or add a few apposite words, increasing their number until he is able to add something from his own experience or even from some other source bearing on the subject. Then he may report an interesting case and ask the views of his fellow members on the subject, and present his own, always modestly and without pretension. Then he will soon come to be a welcome visitor, and later will be wanted to act as Secretary and receive other evidences of the goodwill and confidence of his fellow practitioners which will go to make up the sum of his happiness.

The State and National societies will also claim his membership in due time and it will serve to rub off the cobwebs and keep his mind bright to take advantage of an opportunity of renewing old friendships and mingling with professional friends as well as by listening to papers and discussions. I am not certain that it should be his ambition to attend these latter meetings very early in his career. It will be at least graceful to offer to look after the work of his older confrère while he takes a run to the more distant place of meeting.

But the medical society is not the only place in which he will be brought into contact with professional friends. He will meet them on the road and in consultation, and under all circumstances let his greeting be cordial and his welcome frank and sincere. Jealousies between doctors are the most unjustified of jealousies and yet they are said to be very frequent, especially in the country. I am certain that more than half of these are without foundation, the result of misunderstanding, misrepresentation, hear-

say, and the want of acquaintance. And in the matter of consultation let me give you a word of advice—I say *you* for I believe that most of my audience are general practitioners: Do not be too much in a hurry to call in the consultant from the city. First call upon your neighbor and exhaust the local resources before you send for the specialist from town. You may accomplish as much for your patient, while you will cultivate good feeling and friendship which will react favorably on yourself.

The first duty of the general practitioner is to his patient, but his duty does not end here. He has obligations to the community also in which he lives. My general practitioner, or the one whose picture I am endeavoring to draw, has been educated above the level of the majority of the laity with whom he associates. He has been educated in a direction which gives him knowledge how to guard the health of the community. He should, therefore, take an interest in what concerns it. He should be on the alert to detect violations of hygienic laws, should call attention to such violations and suggest measures for their correction, as well as be ready to advise on matters connected with public hygiene. He should do this in a simple, dignified manner, not ostentatiously or with a desire to exploit himself. It is by attention to these collateral matters so intimately associated with the interests of his patients that he rises above the routinism which hinders his development and prevents his taking the position he deserves among the leaders in his community.

Is the general practitioner to be denied opportunities of social intercourse? By no means. The attainments with which we have equipped him especially adapt him for social relations, and we have seen that it is partly that he may appear at advantage, socially, that we have so equipped him. He will, however, be somewhat limited in this respect. His time is too valuable. I do not see why the general practitioner should not stop for a few minutes in passing the house of a patient for afternoon tea. It will refresh him and brighten him. The same may be said of the evening reception. A prolonged stay at either function he can scarcely afford.

What are the compensations of the general practitioner? The answer to this question depends somewhat upon what meaning is put on the word "compensation." If it means money return then must he often be disappointed, for it is generally conceded that the general practitioner is often poorly paid in money. If, however, he is willing to take as a part of his reward the pleasant consciousness of well-doing his pay is commensurate with his good work. To hold an honorable position in the community and to be looked up to is a privilege for which many would gladly give money, but position such as falls to our ideal is not to be bought. It is only to be obtained from the vantage-ground of the qualifications of the thoroughly educated physician, imbued with the feeling that his calling is a lofty one and that in its unselfish exercise he is approaching a step nearer that estate which has caused him to be compared many times to the gods of heathen mythology as well as to Him who is called the "Great Physician."

The conception I have endeavored to present to you may be called visionary and difficult of realization. I admit that it is a high ideal, and that it may not be attained by each and every one. It may, nevertheless, be the aim of all, and that it is not unattainable is proven by numerous instances. Perhaps the highest exemplification of what I desire to be aimed at was Sir Thomas Brown, the author of "Religio Medici." Sir Thomas was a country practitioner in the strictest sense of the term, and lived in the first three-quarters of the Seventeenth Century (1605–1682), during fifty years of which he practised in the town of Norwich, England, and by his literary productions, of which "Religio Medici" is the most important, exhibited literary attainments equal to the highest of his day. These in no way interfered with his practice, which was very extensive, and many persons came from a great distance to consult him. The Rev. Mr. Whitefoot, his intimate friend for thirty years, wrote of him, "He was parsimonious in nothing but his time, whereof he made as much improvement with as little loss as any man in it; when he had any to spare from his drudging practice, he was scarce patient of any diversion from his studies; so impatient of sloth and idleness that he would say he could not do nothing." Note that his practice was characterized as "drudging," yet he understood most of the European languages, the Latin and Greek critically. "He was so curious a botanist that beside the specifical distinctions he made nice and elaborate observations, equally useful as entertaining." In other respects he fulfilled our ideal of the general practitioner. He left a comfortable, but no great estate to his wife and children, acquired by his own industry. He showed also that even at that early day the medical education had the same liberalizing effect on religious thought that it has to-day, in witness of which, let me read the following extract from his writings: "Nor must a few differences more remarkable in the eyes of man than, perhaps, in the judgment of God, excommunicate from heaven one another. Take our opinions together and from the confusion thereof there will be no such thing as salvation: for first the Church of Rome condemneth us: we likewise them; the Sub-reformists and sectaries sentence the doctrine of our Church as damnable: the atomist or familist reprobates all these, and all these them again. Thus we go to heaven against each other's wills, conceits, and opinions, and with as much uncharity as ignorance do err, I fear, in points not only of our own, but of one another's salvation." These are but a few of the many attainments of this truly great man. For a further account of him I commend to you one of several excellent biographies which are extant. His life and writings should be familiar to every medical man.

Nor does the novelist fail to paint us good pictures of the general practitioner. To say nothing of the oft-quoted Ludgate in George Eliot's "Middlemarch," we have a picture by Sarah Grand in the "Heavenly Twins" of Dr. Galbraith, who, though referred to by the author as a specialist, was really a general practitioner of the type we admire; and the book will repay the medical reader from this standpoint. Elizabeth Stuart Phelps has given us in Dr. Zay an admirable type of the woman general practitioner, albeit she was a homeopath. She

was possessed of all the accomplishments and all of the noble qualities which go to make up our ideal, and her work was full of the nobility of purpose and the happy results which fall to it.

In all word pictures of the physician by lay authors we meet incongruities and errors which fall unpleasantly on the ear of the educated medical reader, but this must be so long as the author is not himself a medical man; and until the latter, at the same time a skilled novelist, furnishes the ideal one, we will be dissatisfied with the physician in the novel. Ludgate is, perhaps, the best, but scarcely better than Dr. MacClure of Drumtochty, as depicted by Ian MacLaren in his beautiful and touching story, "Around the Bonnie Brier Bush," and no discourse on the subject of the general practitioner is complete without a reference to it. Weelum MacLure accords well with our ideal of the general practitioner, having been "chest-doctor and doctor for every other organ as well, accoucheur and surgeon, oculist and aurist, dentist and chloroformist, chemist and druggist." I believe the story of this "scarred veteran in the service of his patients," this self-forgetful doctor, will do more to lift up tbe heart of the physician than the creation of any other novelist. This may be because, as Dr. Watson informs us, "the character was not a fiction, but based upon the knowledge of four country doctors, either one of whom might have sat for his hero." What a privilege to be a member of a profession in which such men abound; what an honor to be one of those from whom such a type is drawn. Well may we glow with pride at the universal recognition it has received, and while taking new courage from the contemplation of such a life, let us not fail also to allow our hearts to be softened by his example and bear with patience the many disappointments and petty annoyances that beset our daily path.

CLINICAL MEMORANDUM.

SUCCESSFUL REMOVAL OF A ONE HUNDRED AND TWENTY-FIVE POUND OVARIAN TUMOR. CÆSARIAN SECTION FOR DEFORMED SPINE AND PELVIS.[1]

By J. G. LYNDS, M.D.,
OF ANN ARBOR, MICH.;
ACTING PROFESSOR OF GYNECOLOGY AND OBSTETRICS IN THE UNIVERSITY OF MICHIGAN.

Case I.—Mrs. E. A. M., aged fifty-four years, married, seven children; age of oldest child, thirty years; of youngest fifteen years. One abortion twenty-five years ago, and another fourteen years ago. All labors were difficult. Was lacerated when first child was born. Began to menstruate at eleven years of age. Periods were regular, lasting seven days. The flow was copious and was attended by considerable pain. Periods stopped nine years ago but appeared again last spring, and continued with more or less regularity up to four months ago. About one year ago she noticed that the abdomen was enlarging, but for some time previous, the patient is uncertain how long, she had noticed a soft enlargement in the lower part of the abdomen. The abdomen steadily enlarged during the past year, and during the six weeks previous to operation, increased in size very much more rapidly than before. She had severe cutting pains in both sides and over the abdomen when making any exertion, such as in walking. The pains subsided in a few hours if she was quiet.

Examination of the patient showed an enormously enlarged abdomen, the full extent of which the photograph does not bring out, the lateral enlargement being very

Fig. 1.

Case of ovarian tumor weighing 125 pounds.

marked. The circumference at the umbilicus was 62 inches, the distance from the ensiform cartilage to the pubes 31 inches. Her weight was 265 pounds. The legs and body were edematous. The pressure on the stomach and thorax was so great that she found it well nigh impossible to retain nourishment of any kind, vomiting up any food almost as soon as taken. She suffered greatly from dyspnea, being unable to sleep except in a sitting or semireclining position. Her heart was weak and irregular and the blood-vessels had little tone. I offered her the chance of an operation, explaining to her that there was no chance whatever without one, and only a moderate one with it. She accepted the situation when she became convinced that she could not be cured by means of medicine, and said the reason she had not come sooner was because the doctor who was treating her had promised to cure without recourse to operation.

On December 10, 1897, after the usual preparation, assisted by Drs. Lahuis and Freeland, I opened the abdomen and found, as I expected, a multilocular cyst containing a great variety of fluids, that from some of the compartments being as thin and clear as spring water, while some was as thick as gelatine, with colors varying from very dark brown or black, to light amber. The contents of a few cysts resembled fecal matter, both in color and consistency, so much so that for a time I thought I had torn through the bowel. The cyst was adherent to the abdominal wall over its entire anterior portion as well as to the diaphragm, stomach, and omentum. I found it necessary to evacuate the contents before I could separate the adhesions, and after considerable difficulty succeeded

[1] Read before the Michigan State Medical Society, Detroit, May 5, 1898.

in liberating the lower portion sufficiently to find and ligate the pedicle. After cutting this I found it much easier to separate adhesions from the bowel, stomach, diaphragm, and upper part of the abdominal wall. When the cyst was removed, the abdominal wall presented a ragged, bleeding surface, shreds of peritoneum hanging from it. There was quite free bleeding from a few of these where the adhesions had been most firm. The shreds were trimmed off, the hemorrhage stopped by ligatures and cautery, the abdomen washed out and closed in the usual manner with drainage, and the patient put in a thoroughly warmed bed.

The large, flabby abdominal walls, and the excessive amount of watery discharge from the drainage-tubes made her a very difficult patient to care for, nevertheless she made an uninterrupted and complete recovery, steadily improving and gaining in strength and weight from the time she came out from under the anesthetic. Six weeks after the operation, when she had gained probably twenty or twenty-five pounds in weight, she weighed 154 pounds, just 111 pounds less than before the operation, so I think I am sufficiently conservative when I estimate the weight of the tumor at 125 pounds, the largest so far as I know that has ever been successfully removed in this State. At the end of this time the patient made the journey to her home, 250 miles away, with no inconvenience, and a few weeks ago she wrote me that she was well and happy now that she was rid of her octopus.

CASE II.—Mrs. D., married, no children, no abortions. When four years of age she began to have posterior curvature of the spine, which steadily increased until she arrived at her present condition. The trouble is thought to have been caused by the arms having been forcibly carried back over her head. She began to menstruate at the age of nineteen, has been irregular, the periods lasting three days, the flow slight in amount, and free from pain. The last period was July 31, 1897, before which time she claims she could not have become pregnant. She had intercourse the first week of August, and subsequently. Examination of the patient shows her height to be 4 feet 9 inches. There is a very marked posterior curvature of the spine, extending down to the lumbar vertebræ, the lowest ribs resting on the crests of the ilia. The abdomen and uterus were enlarged to the size of pregnancy at 7 or 7½ months, and overhung the pubes to the middle of the thighs. The fundus of the uterus rested in its lowest part on the thighs, and the cervix was high up against the diaphragm, forming as complete an anteversion as could possibly exist. The fetal heart, parts, and movements were easily recognized. To replace the uterus in the abdomen and make the uterine and pelvic axes correspond was impossible on account of the short distance and small space between the ensiform cartilage, the ribs, and the pelvis. The patient complained of great disturbance of the heart and of pressure on the thorax. She was greatly exhausted after exertion, was pale, and sickly looking, and ate very little. Her pulse-rate varied from 100 to 130, and was always weak; her urine contained albumin, but no casts. Pelvimetry showed the pelvis to have the following measurements: Between anterior superior spines, scant 9 inches; between crests at widest point, 9¾ inches; between trochanters, 10¾ inches; external conjugate, 6¼ inches. The true internal conjugate, as measured by the finger was calculated to be 3¼ inches. The cervix was high up, resting against the diaphragm beyond reach of the examining finger.

From the above description it will be seen that spontaneous delivery could not possibly occur. Production of

FIG. 2.

Pregnancy in a patient with marked curvature of the spine. Cæsarian section.

premature labor was scarcely to be considered on account of the unfavorable position of the cervix and uterine axis, which would render the use of forceps, version, or embryotomy very questionable, and in the opinion of those who saw the patient, more formidable and dangerous than Cæsarian section. I consequently elected the latter, and decided that the Porro-Mueller modification was the procedure best adapted to the case. One week before the calculated time for labor was selected as the most favorable time for both mother and child, thereby avoiding the complications the onset of labor would be likely to bring.

The patient was prepared for operation on April 29th, in the usual manner for abdominal section. The abdomen was opened, the uterus turned out, a rubber cord thrown around the cervix, and the abdomen closed off by sterilized gauze and towels. The elastic ligature was then tightened, the uterus incised, and the child extracted, the incision passing through part of the placenta, which was located on the anterior surface of the uterus. The child was delivered 4½ minutes after the operation

was begun and not more than 30 seconds after the elastic ligature was tightened, and given in care of Dr. Arneill, who found it somewhat difficult to resuscitate it, possibly on account of the anesthetic. It came out all right, however, and is now well and hearty. The wire serre-noeud was substituted for the elastic ligature, the uterus amputated through the cervix, the stump fixed in the abdominal wound, and the wound closed. The operation, in which I was very ably assisted by Dr. Lahuis, was completed in 10½ minutes. The patient had a slight reaction temperature, reaching 100.8° F. as the highest point. It had varied from normal to 99.8° F., however, before the operation. Forty-eight hours after the operation her temperature and pulse were the same as before. It is now seven days since the operation, and the patient is making a rapid recovery.

In my opinion, this case emphasizes the value as well as the necessity of seeing such patients early, of carefully weighing the value of each and every procedure open to the surgeon, and of electing the one best adapted to the patient, as well as the time most favorable for its performance. The probabilities are that early in pregnancy while abortion might have been given consideration there was not sufficient reason to believe that the extreme anteversion present during the last months would occur, and one would have been justified in the conclusion that a viable child could be delivered, even though it might have to be born prematurely on account of the small and deformed pelvis. The condition, existing however at 7½ months, at which time I first saw the patient, was such as to make the abdominal operation the most favorable procedure. Had the woman gone to full term and labor begun, the operation being then one of emergency, possibly under very unfavorable conditions and surroundings, the chances for good results to either mother or child would have been very much diminished.

Note.—Four months have now elapsed since the operations, and both patients are well and hearty.

MEDICAL PROGRESS.

Actinomycosis of the Face and Neck.—Fantino (*Rev. Gen. de Path. Interne.*, June 20, 1898) finds that actinomycosis of the face and neck is the form most frequently observed at Turin. Caries of the teeth invariably precedes the development of this parasite although no lesions can be found in the mucous membrane of the mouth. The bucco-pharyngeal origin of the disease is beyond doubt, but it is further proved by the preliminary infiltration which is invariably a submucous one. The masseter muscles are generally contracted. Pain is usually slight and fever not well marked. The mycotic grains are a pathognomonic symptom, but they are rarely found even after repeated examinations. The lesions are more characteristic before the skin is broken and pyogenic cocci introduced. Failure to make a diagnosis in an early stage of the disease may result in the death of the patient since when the mediastinum becomes involved treatment is of little avail. Actinomycosis of the abdomen is usually located in the cecum. There may be ascites but not invariably so, and in consequence the presence or absence of this sign is worth nothing in making a differential diagnosis between actinomycosis and tuberculosis. In the thorax actinomycosis produces no especial signs. It may indeed remain unobserved until the muscles and skin are involved. The woody induration which has been spoken of is not constant and may be lacking in acute cases. It is rather due to secondary infections with streptococci, bacteria coli, etc., than to the primary one. The pus may be thick or serous and therefore presents no characteristic aspect. The sole criterion therefore is the presence of the parasite, and this, as has been said, is found with difficulty. Healing may take place spontaneously but the real treatment is with potassium iodid. Surgical measures are not usually necessary and in many instances total extirpation would be impossible.

Simple Dermatitis of Childhood.—Takvorian (*Gaz. Hebd. de Med. et de Chir.*, September 4, 1898) believes that the cutaneous lesions of young infants which are variously described as intertrigo or erythema, vesicular, papular, etc., are different forms of a simple inflammation of the skin. He therefore proposes to sink these irrelevant distinctions and to class them all under the above heading as simple dermatitis of childhood. Such lesions are common enough in a light form, but grave cases are not lacking, and errors in diagnosis may lead to treatment which will aggravate the trouble.

Artificial Dilatation of the Os Uteri During Labor.—Demelin (*L'Obstetrique*, July 15, 1898) advocates the artificial dilatation of the os uteri during labor when there exists a necessity to hasten the birth of the child. This can be accomplished most readily and satisfactorily by the bimanual method. At any time after the uterine contractions have obliterated the cervix, dilatation needs only to be exerted upon the external os. During pregnancy, and in the absence of labor pains this is a much more difficult procedure but may still be accomplished with patience. Under these circumstances the internal os is the portion to which attention must be given. To dilate this requires a great deal of force except in patients who are moribund, or in those in whom the placenta is situated in the vicinity of the cervix. Other methods to produce rapid delivery give results less satisfactory for the child than does bimanual dilatation. The mother does not need to be considered for cervical lesions, if they are produced at all, are slight. A cardinal principle is never to attempt the extraction of a child by forceps or after version before dilatation either natural or artificial is complete. The physician ought always to assure himself of this fact before applying forceps or performing version, and if dilatation is not complete he should complete it in the manner indicated.

Digital Exploration of the Prostate.—Verhoogen (*La Policlinique*, June 1, 1898) says that digital examination of the prostate gland is neglected. Although only its posterior surface is palpable a careful examination will reveal much of importance. The finger should be well

smeared with vaselin, or better still, with some soapy non-irritating substance. This facilitates examination, protects the finger from fecal matter and is easily washed away; or, if preferred, a thin rubber finger-cot may be used. In the normal state the lower border of the gland is about 4 cm. (1.6 in.) above the anus, while its superior border is twice that distance from the anus. Hypertrophy of the gland is not easily made out by digital examination. It is more readily determined by means of a catheter. If a catheter is slowly introduced into the bladder and as soon as urine flows through it, it is slowly withdrawn, the distance from the point at which water begins to flow to the point at which the flow ceases is a measure of the length of the prostate. By attaching an irrigator to the catheter and slowly introducing the latter these results can be confirmed. Until the eye of the catheter reaches the prostate water from the irrigator will flow out at the meatus. While the eye is in the prostate no water can flow through the catheter, but as soon as it passes beyond the limit of the prostate water will flow into the bladder, whence it may be drawn off through the catheter. The average length of the prostate measured in this way is about 2 cm. (1 in.), the variations being from 1.75—3.5 cm. In old men with hypertrophy of the organ the measurements are often from 7 to 10 cm. (3 to 4 in.). Digital examination of the prostate is especially valuable in tuberculosis and chronic or acute blennorrhagia. In doubtful cases of tuberculosis one often finds by rectal touch nodules of the disease situated in the prostate gland. These at a later period break down and form abscesses, or terminate with cicatricial tissue and resulting in atrophy of the prostate. In the former case the finger introduced into the rectum will find a large, tender prostate in which there are softened areas or fistulæ. In the second case the gland is small, shriveled, and irregularly nodular. The seminal vesicles usually present similar lesions. In chronic prostatitis as in tuberculosis, the prostate is enlarged and sometimes nodular, but in the former the nodules are larger than in the latter, and the gland also feels edematous on pressure. Digital examination is no less important in acute blenorrhagia, for while the symptoms of inflammation in the urethra and bladder are well described by the patient the diagnosis of acute prostatitis is best made with the finger in the rectum. The prostate will be found tender while the sphincter is so firmly contracted that an anesthetic may be necessary. Sometimes an abscess forms which should be incised rectally if it does not break spontaneously in a short time. Otherwise a great quantity of pus may form before its presence is manifested externally. Malignant tumors of the prostate are hard and nodular and are easily made out rectally. In these cases bimanual examination should be employed to determine the size of the tumor and, what it is more important, its mobility.

The Role of the Spleen in Infection.—GOURMONT and DUFFAU (*Revue Gen. de Pathol. Int.*, June 20, 1898) regard the rôle of the spleen in the resistance of infection as still obscure. Different experimenters have reached apparently contradictory conclusions. Splenectomy acts differently according to the nature of the infection, for the reason that the spleen has not a uniform rôle in the presence of all microbial attacks. Against some it is a useful defense, against others it is powerless. The length of time that elapses between the splenectomy and the infection is also of importance in determining the result. Thus a rabbit whose spleen has recently been removed is more sensitive to pyogenic staphylococci than one who for a longer time has been deprived of this organ; but the more recently splenectomized animal can better resist streptococci than his fellow who has been longer without a spleen. The explanation of these diverse results is said to be as follows: The serum of a rabbit, eight days after the loss of its spleen, is found to be microbiophil for the pyogenic staphylococci, while on the other hand it is neutral or possibly bactericidal toward the streptococci of Marmorek. In brief the spleen secretes such substances as it is able for the defense of the body. They are useful or useless according to the character of the attacking germs.

THERAPEUTIC NOTES.

The Cure of Tetanus.—DU HAMEL (*Med. Moderne*, August 10, 1898) narrates a case of tetanus occurring in a boy aged fifteen and produced by a pistol-shot wound between the thumb and index-finger. Owing to the boy's cries the wound was not properly cleaned and some time later symptoms of tetanus set in. He was taken to the Pasteur Institute and in addition to hypodermic injections of antitetanic serum three cubic centimeters of a similar fluid was injected in each side of the brain near the fissure of Rolando. At the time the injections were made the patient was in a condition of strong opisthotonos. The contractions gradually diminished though they did not entirely disappear for some days. In three weeks he was out of the house. A more striking instance of the therapeutic value of this serum could scarcely be asked for. As a preventive 10 to 20 cubic centimeters should be injected at the time the wound is received. If symptoms of tetanus set in injections should at once be commenced and repeated at intervals until a cure is effected.

Treatment for Fracture of the Olecranon.—SALLE (*Gaz. Heb. de Med. et de Chir.*, June 5, 1898) speaks of the advantages of massage in the treatment of fractures of the olecranon. The repeated examinations which it necessitates familiarize the operators with the minute details of the fracture and with its symptoms. It lessens pain and muscular contraction and so makes diagnosis more accurate. As the treatment of a contusion and a fracture of the olecranon is one and the same the difference of diagnosis between these two is unimportant. Massage renders the prognosis more favorable and the complications which often follow continuous immobilization are avoided.

The duration of treatment by massage does not exceed that of other procedures; osseous suture for example. The results are most satisfactory.

THE SURGEON-GENERAL OF THE ARMY AND THE NATIONAL RED CROSS SOCIETY.

ANOTHER clash between the Surgeon-General of the Army and the Red-Cross Society seems to be imminent. The latter organization has asked the privilege of establishing Red Cross hospitals at various points in Porto Rico in connection with the United States garrisons. To this General Sternberg has replied that such an arrangement is entirely unnecessary, as the medical department of the army is amply equipped for all work of that nature.

It will be remembered that when the army was being organized for the invasion of Cuba and the expedition was about to start, the Red Cross made an application to send its nurses and hospital supplies as an adjunct to the army nurses and hospitals. To this request General Sternberg made a similar reply to the one he has given them in the present instance. The result was that the Surgeon-General had the humiliating experience of seeing the army surgeons in the field turning perforce to the Red-Cross hospital, to the Red-Cross supplies, and to the Red-Cross nurses to succor them in their dire distress as the only means of securing proper care for a large number of the sick and wounded soldiers. In what Department the responsibility for this inexcusable and unwarranted necessity rests has not yet been determined, but owing to some lack of foresight, or neglect, or incompetency, General Sternberg's answer to the Red-Cross proposition was not justified by the results. And yet, theoretically, General Sternberg's attitude at that time was correct, and theoretically the position he has again taken is correct. It is the duty of the medical department of the army to see to it that the army is equipped with a proper force of surgeons, assistant surgeons, and ambulance corps. It is the duty of the medical department to provide ample supplies of hospital and surgical necessaries for all emergencies. It is its duty to see that the health of the soldier is protected at every possible point. That is what the medical department is organized for and why it has its existence. The head of that department would, therefore, be wanting in self-respect if by act or word he admitted for one moment that the department was not competent to take care of the army.

It must be admitted that the department lines in the army are very sharply drawn, and in the execution of military orders there is a routine and a complicated machinery by which the orders pass the line from one department to another, which causes seemingly unaccountable delay and has brought the system into disrepute and stigmatized it as "red tape." A man of administrative force and ability, however, who appreciates the fact that the essence of a promulgated order lies in its execution, in times of emergency will break through the barriers of red tape and follow up his written order with a force and determination that will witness its execution before he relinquishes his pursuit. It was apparent on more occasions than one in the recent conflict that the man who metaphorically took the quartermaster or the commissary officer by the throat and insisted that his order should be executed whether any other order was or not, had his way. To have taken every quartermaster or commissary by the throat would have required a surgeon-general possessed of a 1000 hands. A small staff of able administrative officers would have met all emergencies, and obviated the sad shortcomings which robbed the medical department of the glory which it should have achieved. *Verbum sap.*

If the Red Cross is to be denied the opportunity of supplying gaps and shortcomings and shortness of supplies in nurses, hospital necessities, and hospitals themselves, it behooves the medical department to make surer of its ground than it did before Santiago.

VIRCHOW'S HUXLEY LECTURE.

THE second Huxley lecture delivered before the Charing Cross Medical School, London, under the chairmanship of Lord Lister, by the world-renowned savant Rudolph Virchow may be regarded as the most important retrospective contribution to medicine of the year. From the high vantage ground of a half-century's experience and the lofty pinnacle on which he has been placed by his many *bahnbrechende* contributions to science he has scanned with philosophic eyes the past and with wizard glasses searched the future in a most illuminating way.

Having passed in brief review the factors that brought about deliverance from the pernicious humoral pathology the lecturer went on to show that the greatest difficulty in the advance of biology has been the tendency of its disciples to set in the forefront of their inquiries the search after the unity of life. Hence arose the doctrine of vital energy and of spontaneous generation. Every one knows that it was Virchow's own investigations that emancipated science from this bondage. We envy his auditors the opportunity of hearing from his own lips a recitation of the processes and stages by which he was led to the conviction and proof that every living organism is not an individual but a social mechanism, and, like every organ and tissue, contains cells which are composed of organic chemical substances but which are not themselves alive. Application of this cellular theory permits us to lift veil after veil from the mysteries which have shrouded the doctrine of heredity even though it does not solve completely all the problems of that science. In reference to heredity the lecturer embraced the opportunity to state positively his belief in the hereditary transmission of acquired conditions.

With regard to the subject of parasitism he referred to the fact that the progress of scientific observation was retarded for centuries by the prevalence of the assumption that disease in general was regarded as a parasite. The recognition that the presence of a parasite meant harm to its host indicated the dawn of the true interpretation of this most important class of diseases. Study of the parasites led to the detection of parasitic protozoa by which the occurrence of the tropical fevers may be explained, and eventually their prevention successfully encompassed. It is necessary to distinguish between the cause and the essential nature of infectious disease, the latter of which is determined by the reaction of the tissues and organs to the microbes. Moreover that there is a relation between the smaller parasites and the diseases determined by them. Investigation of the mode of action of infection has already led to Listerism and to the introduction of serum-therapeutics, but apparently we are only on the threshold of the arena thus opened.

In closing Virchow referred to the problem of immunity and artificial immunization, the solution of which the whole world is awaiting with anxious impatience. Unfortunately the question has not yet emerged from the conflict of opinion and still less is the secret of immunity itself revealed. Even if everything points to the view that immunity is based on the condition of the cells and the juices of their parenchyma, we must still become accustomed to the thought that only the next century can bring perfect light and certainty on this point. Before then we must at least have succeeded in finding a way of strengthening the cells in their fight with bacteria by means of immunity. Those who have looked askance on the therapectic use of tissue-juices and the derivatives of secretions such as the semen may hearken to these words: "Though we are not yet in a position to pass final judgment, every one who is sufficiently unprejudiced must admit that they have in many cases been good. The source of all these substances is the cell-activity of living tissue, and that which is secreted thereby. Its therapeutic or pathologic action on individual organs or tissues can only exercise a regulatory influence on cell activity."

ECHOES AND NEWS.

Meeting of the Southern Surgical and Gynecological Society Postponed.—The Southern Surgical and Gynecological Association has postponed its meeting at Memphis, Tennessee, until December 13, 14, and 15, 1898, an account of the prevalence of yellow fever.

The Use of Tuberculin in France.—The general council of the Côte-d'Or has passed a resolution calling upon the

public authorities to pass a law rendering it compulsory for all animals intended for purposes of food or for milk supplies to be treated previously with tuberculin, and urging the observance of all sanitary measures directed to the stamping out of bovine tuberculosis.

The Physician Not Responsible for Notification of Birth.—A French legal tribunal has lately given judgment to the effect that the medical attendant in cases of childbirth is not obliged to notify the authorities of the birth, provided the father is present. A midwife was recently prosecuted for omitting to supply a birth-certificate, but she was acquitted on the ground that the father was present at the time.

The Death of Dr. Toscani.—Dr. Davide Toscani, professor of legal medicine in the University of Rome, died after a long illness at Rome, September 15, 1898. About twenty-five years ago he established the Municipal Office of Hygiene at Rome, and was its director for twenty years. The great improvement which has taken place in the sanitary condition of that city during this time is largely due to his labors.

The New York Obstetrical Society.—At the annual meeting of the New York Obstetrical Society, October 11, 1898, the following officers were elected for the ensuing year: President, Dr. W. R. Pryor; vice-presidents, Dr. Le Roy Broun and Dr. Edwin B. Cragin; recording secretary, Dr. Joseph Brettauer; assistant recording secretary, Dr. E. E. Tull; corresponding secretary, Dr. George W. Jarman; treasurer, Dr. J. Lee Morrill; pathologist, Dr. George C. Freeborn.

Dr. McGee Still in Service.—Assistant Surgeon Annita N. McGee, U. S. A., has been ordered to proceed from Washington, D. C., to Fort Monroe on official business pertaining to the medical department of the army, and on the completion of her duty to return to her proper station. Dr. McGee has had charge of the selection and appointment of female nurses employed by the army. She is the daughter of Professor Simon Newcomb, U. S. N., and the wife of Professor McGee of the Geological Survey, and has the distinction of being the only woman to hold a commission in the U. S. Army.

Health of the Troops at Santiago.—The number of cases of sickness from all causes has slightly increased during the past week, while the number of cases of fever remains about the same with the general tendency to decrease. The daily average of those on the sick-list has been over one thousand. Eleven deaths from all causes are reported. Of these deaths two each were due to typhoid, malarial remittent, and yellow fevers, one each to chronic dysentery, typhoid pneumonia, bilious fever, and delirium tremens, and one to malarial remittent fever accompanied by acute dysentery.

Obituary.—Dr. Nathan Smith Lincoln, one of the oldest and most prominent physicians of Washington, D. C., died at his residence October 14th, at the age of seventy. Dr. Lincoln was the grandson of Dr. Nathan Smith, who was the founder of the medical schools of Yale and Dartmouth. Dr. Lincoln was graduated from Dartmouth College in 1850, and from the Medical Department of the University of Maryland two years later, removing to Washington in 1854. During the Civil War he was surgeon-in-chief in the military hospital at Washington. Since then he has held various high offices in the District and National medical societies, and was one of the vice-presidents of the Ninth International Medical Congress.

A Case of Tetanus Cured by Antitoxin.—A young man of Passaic, N. J., recently fell from a hotel window and crashed through a skylight. Besides many minor injuries sustained, a large portion of the calf of one leg was torn completely away. Conservative work was done and the wound gave every promise of healing kindly when suddenly tetanus developed. Antitoxin serum was injected hypodermatically but without effect. As a final effort it was decided to resort to the heroic measure of trephining the skull and injecting the antitoxin directly into the brain tissue. This was accordingly done, with the result that almost immediately there was a relaxation of the muscles of the jaw. Since then improvement has been steady and constant.

The Handwriting of Medical Men.—A writer in a recent number of *Medicin Moderne*, after expressing his sympathy with the pharmacists whose difficult task it is to decipher illegible prescriptions, adds that the matter has attracted the attention of the Dean of the Medical Faculty of Paris. The execrable handwriting of many French physicians is thought to be a menace to the public, and the Dean is reported to have said that he would take the earliest opportunity of bringing the matter to the notice of the faculty. The pharmacists of America will doubtless sympathize with this movement. Typewritten "copy" is saving the dispositions and morals of medical editors, but relief for the pharmacist would seem to be a much more difficult matter.

Poisoned from Eating Shrimps.—Forty cases of acute poisoning from eating shrimps occurred at St. Anne's-on-Sea, near Blackpool, England, during the third week in September. The symptoms were those of an irritant poison—diarrhea, vomiting, and severe pain, especially in the bowels, being marked. Happily no fatal cases occurred, thanks to prompt medical assistance. The shrimps were potted and had been cleaned and cooked in the usual manner, and converted into paste by the aid of butter. There is no record of an analysis of the shrimp paste having been made. It would seem probable that, as the paste was fairly fresh its ill effects were due to an organic poison, ptomain, or decomposition product consequent upon the excessive heat.

Story Regarding Dr. Shippen of Philadelphia.—A writer in *Lippincott's Magazine* tells a new anecdote of Dr. Shippen of Revolutionary fame. He left his house early one morning and was hurrying down the street, when he noticed a singular and ferocious looking man, whose gaze was fastened upon him. With instinctive politeness Dr.

Shippen smiled, raised his hat and passed on. Then, a shot was heard. Turning quickly Dr. Shippen found that the stranger had just left his home with the insane intention of killing the first man he met. Dr. Shippen was the first man; but his absolute fearlessness and constitutional, as well as cultivated courtesy, had put the man off his guard, and the next passer-by had caught the bullet intended for him. That smile and bow had saved his life.

Smallpox in New York State. — Twenty-one cases of smallpox have appeared within the last two months at McLean, a village twelve miles from Ithaca. The contagion was carried there by a traveling show, one member of which was taken ill and confined in the isolated hospital at Ithaca. The cases have been of such a mild character as to excite little suspicion. The disease was diagnosed and treated as an ordinary skin eruption. It was only recently that its real nature was suspected, and an investigation ordered by the State Board of Health. An inspector was sent to the village who examined the cases conjointly with the members of the Ithaca Board of Health and pronounced them to be genuine smallpox. All suspected cases were at once quarantined, but as the entire village has been exposed to the contagion for a month many more cases are expected to develop.

An Ethical Specialist.—A veteran specialist of a neighboring city desires to make it clear that he stands ready to observe the golden rule—of doing to others as he would be done by—toward his fellow practitioners. He has sent his card to the doctors of his community with the following foot-note: "In strict accordance with professional ethics, patients referred to me for diagnosis, or suggestions regarding remedial measures, will not then, nor thereafter, receive treatment at my hands unless by professional request or consent." Why this gentleman, who has for years had the reputation of being jealous of the rights of others, should feel called upon to make this declaration of ethical pronouncement, we know not. One inference we may be pardoned for making is that some of his neighbors are "a little off" in their consultation ethics.

Alleged Antagonism of Malarial Fevers and Asiatic Plague.—A letter to the London *Lancet*, August 20th, from Bombay, points out that there is an increase of plague in several inland towns and a relative freedom from that disease at Calcutta. The writer says that he believes there will be found to exist an active antagonism on the part of malarial infection against the plague. "It is very suggestive," he says, "that inoculation for plague should exert a favorable influence on the subject of malarial disease. Many persons who have periodically suffered from febrile attacks of malarial character have remained free from them after inoculation. The antagonism of one toxin to another, or to the development of certain forms of bacilli or other micro-organisms, is little known, but it is probably on these lines that some of the greatest achievements in experimental science have yet to be made known."

The Extortions of Foreign Manufacturers.—In commenting recently upon this subject the *Bulletin of Pharmacy* says: "The following prices tell the story of the unmitigated extortion to which the general public, the drug trade, and the medical profession of America have been subjected for nearly two decades. The first column gives the prices per ounce charged the retail druggist in Canada; in the second appear the prices paid by the American druggist and dispenser:

Drug.	Canada.	U. S.
Phenacetin	0.25	1.00
Sulfonal	0.25	1.35
Trional	0.90	1.50

"This list of three drugs, be it remembered, represents only an insignificant and paltry fraction of the patented synthetic chemicals which have been poured in upon the American market chiefly by German manufacturers. A complete list would cover easily two or three of our pages, and in nearly every case the same glaring disparity prevails between the moderate prices ruling in Germany, France, England, and Canada, and the outrageously extortionate prices imposed upon the same articles in the United States. We earnestly urge our readers to do something more than merely curse the monopolists. Write the congressmen and senators. Write the commissioners, and lend a helping hand to the relief of the public from extortion and spoliation."

Little Malaria in the Porto-Rican Army.— Dr. Richard C. Cabot, who had charge of the hospital relief ship "Bay State" during her recent trip to Porto Rico to succor the Massachusetts troops and bring back the sick and convalescent, says in a letter to the *Boston Medical and Surgical Journal* that he examined the blood twice in 277 cases collected from all parts of the island, once for malaria and once for the Widal typhoid reaction. Continuing, he says: "To me the results of these examinations were very surprising. Just before leaving Boston I had been examining at the Massachusetts General Hospital the cases brought from Santiago by the "Olivette" and the "Bay State." A large proportion of these cases showed in their blood the organisms of estivo-autumnal malaria, and I had become so used to seeing the crescentic parasites in case after case that I listened with polite skepticism to the report of the doctor at Guanico, who said to me that he had seen no malaria in his regiment. When my examination for malaria began to turn out negative in case after case, I could hardly believe my eyes, and repeated the examinations as carefully as I knew how. The result was the same, and out of the whole 277 cases examined I found malarial parasites in only two cases—one the tertian, and one the estivo-autumnal organism. Since the crescentic forms of malarial parasites remain in the blood for weeks despite the administration of quinin, I do not think that these negative findings were due to the fact that almost all the patients (typhoids included) had been taking quinin in large doses. We were highly gratified to hear before leaving Ponce, that owing to my findings and those of Dr. T. Leary, the

wholesale use of quinin in all fevers at the Ponce United States Hospital was stopped. This alone would, I think, have made the "Bay State's" trip worth while."

CORRESPONDENCE.

THE ROLE OF THE PUBLIC CARRIAGE IN DISEASE CONTAGION.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—The other day I was an eye-witness to the transportation of a consumptive from one residence to another in an ordinary hack. It suggested to my mind what part this every-day vehicle plays in disease contagion. At most funerals the hack is brought into use. Relatives who have been exposed to the germs of such diseases as diphtheria, scarlet fever, or perhaps tuberculosis, occupy these carriages. The next day, or even on the same day of such a funeral, these very hacks are used by a different set of individuals.

I ask, then, what can prevent people exposed to infection from carrying pathogenic germs to and depositing them in the upholstered parts of the carriage? Often these very vehicles are brought into play as primitive ambulances whereby patients are carried from the station, from the gutter, or from the hotel to private residences or even hospitals. At the emergency the nature of the trouble is not always known. And here, again, many a patient suffering from the prodromes of some contagious disease is dumped into a hack and hurried off to his home or where not. The individual who occupies that hack next is liable to infection.

Yours truly,

A. HOLLINGWORTH, M.D.

PAWTUCKET, R. I., October 10, 1898.

WOUNDS OF THE HEART.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Your editorial of October 8, 1898, on the subject of "Wounds of the Heart" interested me very much. In my opinion no domain in surgery, at present unmarked, promises so much in brilliancy of result to the skilful and daring operator.

Some years ago I made a series of experiments in heart wounds, using cats as the subjects. The results apparently showed that a fatal issue may result in one of two ways. Certain wounds, especially those near the apex, were immediately and instantly fatal, the animal dying as suddenly as if stricken by lightning. Though I never succeeded in determining the cause to an absolute demonstration, my inference was and is that the involvement of the intracardiac ganglia was the reason of the sudden fatal issue. These cases, of course, are at present without a vestige of hope, as the subjects are dead, practically, from the time of the reception of the injury. There is, however, a second class which promises brilliant results. I found that when the auricle or ventricle was penetrated, there being but a small wound in the pericardial sac, the blood was poured out until the sac was filled. The incessant action of the heart prevented the formation of an occluding blood-clot. The pericardial sac being filled with blood, the heart was simply swamped in blood and its actions hindered by it. Time and again I have seen a heart which had practically ceased to beat, resume beating with wonted force and rhythm when the pericardium was incised and the blood turned out. In this class of cases there are two direct causes of a fatal issue: (1) Interference with heart movements by blood in the pericardial sac, and (2) fatal hemorrhage.

The indication is plain. Resect the fifth or sixth rib, or both, incise the pericardium, turn out what clot may be present, and close the wound in the heart structure. Most patients will die before they come to the hand of a competent surgeon, but in a certain number, such as the one detailed in the editorial mentioned, there will be a large enough opening in the pericardium to allow the escape of part of the blood, thus obviating fatal interference with the action of the heart.

Thanking you for your indulgence, and hoping that some American surgeon may apply these principles to actual practice, I am

Yours very truly,

V. M. REICHARD, M.D.

FAIR PLAY, MD., October 15, 1898.

SOME GUIDES TO THE DIAGNOSIS AND DIFFERENTIATION OF APPENDICITIS.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—Since it is a recognized fact that the diagnosis of appendicitis is often very obscure in the early stages the following sign which has so often served me well, may prove of value to other surgeons. Realizing how well Hilton's law in regard to the nerve-supply of joints (a nerve which supplies a joint supplies also the muscles controlling the joint and the skin covering it) applies to the abdomen, it has occurred to me to put it to practical use in localizing as far as possible the side and situation of an inflammatory process in the abdomen.

The books tell us to look for a contracted rectus muscle on the one side, but how difficult it often is to make out that one is contracted or slightly so and the other relaxed. The sign I would point out is this: Test the epigastric or rectus reflex on each side and it will be found that the right rectus being already contracted or partially so will not respond while the left will. The reason is that the inflamed appendix already has called upon this reflex to protect it.

Among several cases in which I have used this sign with great success, I will briefly recount a recent one: A girl, aged eleven years, was attacked with severe diarrhea after eating peanuts. On the second day she screamed with pain on and after passing urine, and her abdomen in the pelvic region was tender to the touch. On each side corresponding to about 1½ inches below McBurney's point she winced upon pressure but on neither was the pain more acute than on the other. The abdomen seemed perfectly pliable and pain was complained of in no other region. Temperature varied from 99° to 101° F. for

three days following the diarrhea, pulse from 80 to 100. A catarrhal condition of the bowels was present as was evinced by the many dejections of dirty-green and thin stools. On one occasion during the first 24 hours a slight vomit occurred. No satisfactory symptom of appendicitis could be found. I pointed out to my colleagues, Drs. Hart and Martin, the sign as described above. We immediately applied it to the case in hand and found it of the greatest value; the diagnosis was promptly made, and I operated and removed successfully a gangrenous appendix. The patient is now perfectly well.

I was called recently in consultation with Dr. C. F. Gardener to see a patient who had had several attacks presumably of appendicitis, and, being tired of their repetition, wished an operation. He was apparently just recovering from an attack, and his physician informed me that at the onset he had usually given immediately a large dose of salts which cut short the attack. On examining the patient I found a tender spot below the McBurney point, but nothing abnormal could be detected. I discovered, however, that I could pass my finger with the greatest ease up the inguinal canal, and at the internal ring which was easily felt the tender point was immediately encountered, and the patient said at once: "That is the place." This corresponded exactly with the spot he had indicated externally. On the left side a condition somewhat similar was detected but the parts were less relaxed. The explanation at once suggested itself that on several occasions he had suffered from a beginning hernia, but the peristaltic action caused by the salts had withdrawn the bowel from the inguinal pouch. No operation was advised.

GERALD BERTRAM WEBB, M.D.

COLORADO SPRINGS, COL., OCTOBER 14, 1898.

A QUACK IN TROUBLE.

To the Editor of the MEDICAL NEWS.

DEAR SIR: W. G. Brown, attorney for Mr. Edward S. Hedges, Secretary of the American Horse Exchange, has begun an action against E. H. Bemis of Glens Falls, N. Y., to recover $25,000 damages for the loss of his client's eyesight, through unskilful, unscientific, and grossly negligent treatment. Bemis is a layman, who has made himself rich by advertising that he can cure all diseases of the eye, from hordeolum to glaucoma. His victims have been many, and are drawn from all grades of society. For nearly a year Mr. Hedges had been gradually losing his sight, due to atrophy of the optic nerve. He was under the care of an eminent oculist in New York City, who, curiously enough, would not promise a complete restoration of sight. The wonderful Bemis, however, would promise anything, and to Mr. Hedges these alluring promises loomed up like a life-preserver to a drowning man. A few days after his arrival at the sanatorium a colored waiter from the "Sagamore" on Lake George came down to be treated for what was probably a gonorrheal ophthalmia. Bemis, not being a medical man, is probably ignorant of the virulence of the industrious gonococcus when turned loose in a suitable medium. Anyway, he took no antiseptic precautions, but used the same pipette and solutions in the eyes of all the patients, with the result that five days after the advent of the negro there were nine fresh cases of "conjunctivitis." Bemis was profuse with assurances that they had simply taken cold and would be all right in a few days; but when Mr. Hedges consulted a regular physician and learned that he had acquired a dangerous and contagious disease, he told his fellow sufferers, and there was a general stampede for New York. This prompt action undoubtedly prevented the total destruction of many eyes, but there followed weeks of anguish and anxiety, together with pecuniary loss by reason of incapacity for business, a loss which Mr. Hedges estimates in his case at $25,000.

Yours truly,

JOSEPH ALAN O'NEILL, M.D.

NEW YORK, October 10, 1898.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

HOSPITAL ABUSE—DAMAGES AGAINST A PHYSICIAN—FATAL CASE OF TETANUS TREATED WITH ANTITOXIN—SICK-SOLDIERS' FUND BENEFIT—NOTES ON CHARITIES AND CORRECTION COMMITTEE—AN ARREST FOR PRACTISING WITHOUT A LICENSE—PERSONAL NOTES—HEALTH-BOARD STATISTICS.

PHILADELPHIA, October 19, 1898.

THE *Philadelphia Medical Journal*, in an editorial, entitled "Another Phase of Hospital Abuse," describes the unfortunate experience of a physician who endeavored to have a patient suffering from purulent conjunctivitis admitted to a hospital. After being refused admission at several which receive State aid, the patient was finally taken care of by a denominational institution, which, because it is denominational, does not receive support from the State.

In regard to hospital abuse, the agitation which was started last spring seems to have been utterly devoid of results, probably because the question was not discussed on its broad issues but in a limited way. There are several causes for this abuse, among them being: First, a desire for large attendance at the clinics in order to secure liberal contributions from the State and individuals on the recorded number of patients treated. Second, a desire for large attendance in order to secure among the number an average of rare cases for presentation to medical societies or students. Third, a desire for the honor (?) of treating the largest number of patients. The fruits of this system are: (1) Necessarily limited attention paid to many worthy cases because of the time required to treat the enormous number of patients at the clinics. (2) Deprivation of many fees to physicians to whom these patients would ordinarily go. (3) The creation of a pauper feeling among the community. (4) Free consultations by unscrupulous physicians, who, nevertheless, charge the patient "for Professor Blank's opinion."

The remedy applicable to the first cause is appropriations based upon the number of patients treated in the wards of hospitals, and not upon the dispensary cases

where expenses are *nil*, most hospitals charging at least the cost of prescriptions. For the existence of the second cause there is no excuse. The *rare* case is unsuited for presentation to students, and to the medical men it will eventually be presented independent of the clinic. What excuse can be offered for the third cause? Human nature seems to be its chief factor. Why does the physician in charge permit himself to be deprived of just consultation fees? Possibly because his directors complain that "the clinic is falling off." Why does the assistant continue to treat these cases which should legitimately be his? Possibly because he prefers to gain some experience rather than wait hopelessly for the very people he is treating at the dispensary. So the endless chain goes on, and until physicians realize their ultimate loss in pursuing this policy it doubtless will continue to go on, and meetings for its suppression will continue to be a farce.

Damages to the extent of $3500 were awarded the plaintiff in an action brought by William H. Forse of Norristown against Dr. H. F. Scholl. The plaintiff had been left a cripple owing to the alleged unskilful treatment by the doctor, whose diagnosis and treatment of the case were afterward criticised by a hospital physician to whom the plaintiff went for relief.

A fatal case of tetanus occurred last week in which antitoxin proved of no avail, though administered early. The patient, a boy fifteen years old, had his finger stamped upon while playing football, and four days later developed symptoms of tetanus. The finger was amputated, and after the administration of antitoxin the boy appeared to improve for forty-eight hours, at the end of which time tetanic convulsions came on, causing death by exhaustion the tenth day following the injury.

The Medico-Chirurgical Hospital is to have a benefit performance next Tuesday afternoon at the Academy of Music in aid of the Sick-Soldier Fund. President McKinley and other prominent visitors to the Peace Jubilee are expected to be present.

Councils Committee on Charities and Correction have decided to increase the salary of its "out-door" physicians from $240 to $480 a year. An item of $28,000 for the support of feeble-minded children in the institute at Elwyn was amended to read "or other institutions," as the Board is having trouble with the institution, and wishes to be able to send the children elsewhere in case friction continues. Dr. J. William White sent in his resignation as a member of the surgical staff of Blockley, and Dr. David Bevan resigned his position as out-door physician for District B.

H. P. Lorman of Philadelphia was taken to Carlisle by a State detective and there lodged in jail, having been indicted by the Grand Jury for practising medicine in Cumberland County without a license.

Dr. Abram Jacobi of New York delivered an address before the College of Physicians, Monday, October 10th, taking for his subject "Some Preventatives." He spoke of the prevention of puerperal fever, gave some advice as to infant-feeding, and discussed at length the prevention of premature senility by careful rules in regard to eating, drinking, exercising, and sleeping, and in this connection decried the "leave-to-Nature" theory of curing disease.

The Board of Directors of City Trusts have made the following appointments at the Wills Eye Hospital: Dr. Albert C. Snell to be resident-surgeon for one year from November 1st; Dr. James Thorington to be assistant-surgeon under Dr. Risley; Dr. Walter L. Pyle to be assistant-surgeon under Dr. Behrens.

Dr. William Pratt Read, a graduate of Princeton and of the Medical Department of the University of Pennsylvania, died October 10th, aged fifty-one years. Dr. Read was Grand Medical Examiner of the Order of United Friends, a Mason, and one of the founders of the American Legion of Honor.

The total number of deaths occurring in Philadelphia, as reported at the Health Office, for the week ending October 15th was 331. The total number of new cases of contagious diseases for the week was 333, as follows: Diphtheria, 115 cases with 21 deaths; scarlet fever, 18 cases with 1 death; typhoid fever, 200 cases with 11 deaths.

OUR FOREIGN LETTER.

The Seventieth Annual Congress of German Naturalists and Physicians.

[Specially Reported for the MEDICAL NEWS.]

THE annual meeting of the German Naturalists and Physicians is always one of the important scientific and medical events of the year in Germany and this year's session, which opened at Düsseldorf on September 19th, proved no exception to the rule. A notable feature in connection with the congress was the exhibition of instruments, books, and objects of interest connected with science and medicine. The exhibition illustrative of the history of medicine was especially instructive, all the ages and countries being well represented. An important collection of instruments that had been used by the medicine men of various American Indian tribes, could not help but attract an American's attention and make him wonder if a sufficient amount of care is being taken to preserve a complete collection of such interesting objects in America, where they will have in a few years the special archeological and ethnological interest of belonging to an extinct people.

At 9 A.M., September 19th, the first general session took place in the Imperial Hall of the municipal "Tonhalle." More than 800 people were present, among whom, in the light of the recent unfavorable position taken by the representatives of the German medical men on Doctor's Day at Wiesbaden as regards medical studies for women, it is interesting to note that there were a large number of women. It is but another indication of the gradual submission to the inevitable in the matter of the higher education of women that is growing more and more noticeable throughout Germany, despite the persistent protests of the more conservative. Last year during the session of this same congress at Brunswick, when the question of excluding women from certain of the more exclusively medical sessions came up, Virchow lent all the great

weight of his authority and influence in favor of the fullest privileges for women at the congress. This year the German women interested in science and medicine were in attendance in full force.

PROFESSOR WALDEYER of Berlin in his opening address as President announced the establishment of a formal society of German Naturalists and Medical Men, under whose auspices future congresses are to be held. So far the organization of the yearly meetings has been in the hands of committees appointed annually. Especially of late years, a number of the regular attendants at the sessions have felt the lack of, and discussed in various journals the need of, closer union. This has now been effected.

PROFESSOR KLEIN of Göttingen spoke on "Polytechnic Schools and Universities." This was one of the non-medical addresses, but was interesting to medical men because Professor Klein demanded for polytechnic schools the facilities for giving instruction as practical as the German medical schools are giving at present. Just as the physician from practical contact with cases is able to take up at once the practice of his profession, so the trained mechanician should be able to enter upon practical work immediately after leaving school. As the medical men in their discussion of clinical instruction in medicine at Wiesbaden in April claimed that it is especially from the practical side that there is room for improvement in the present teaching of medicine, this expression of "the way that others see us," a typical example of the common feeling that other people are so much better off than we are ourselves, was very interesting. That professors of the natural sciences and mathematics should demand more practical work for students (as well as the teachers of medicine) is but a pregnant sign of the times in educational matters generally, for theory is losing its precedence to practice all along the line.

PROFESSOR TILLMANS reviewed "The Century in Surgery" in an address of general rather than special interest. Anesthesia, antisepsis and asepsis, and the Röntgen-rays were particularly dwelt upon. Professor Tillmans considers that the future development of surgery now depends on the cultivation of surgical pathology and intimate collaboration with the other branches of general medicine, in order that by earlier and more assured diagnosis new fields of operation may be opened up to the surgeon. Modern surgical technic he considers so perfect that the limits of its application to human ills have been by no means reached as yet. Animal experimentation he thinks has accomplished so much for mankind in the past, in surgery, in serum-therapy, in the study of the etiology of disease, and in so many other branches of medicine that he considers the prejudice against it as *inhuman*. He foresees that the undue limitation of animal experimentation would be a serious detriment to the medicine and the surgery of the future. As Professor Moritz Schmidt in opening the German Medical Congress some months ago took occasion to allude to the same subject it may be seen that the movement is gradually forcing itself upon the attention of German medical men and serious efforts are being made to educate public opinion in the matter and preclude the possibility of inhibitory legislation that would interfere with scientific investigation.

The close of Professor Tillmans' address took up the subject of military surgery and his sketch of its future would seem to indicate, as one of the German papers puts it, that "the cry of peace from the Neva had found no echo upon the banks of the Düssel." Despite the Czar's invitation to disarm, Professor Tillmans, a General Oberarzt in the German army, discussed confidently the surgery of the wars to come. As at the German Surgical Congress in April the dum-dum bullets, *i. e.*, the nickel-covered bullets, with unsheathed points, that the English have been using in India, were a subject for the severest condemnation on the score of inhumanity. It was suggested that the use of such missiles should be especially interdicted by international law.

Despite the efficiency of modern firearms Professor Tillmans was able to show by a comparison of the losses in battles at the beginning of the century with those of more recent years—the mortality at Leipzig, Borodino, and Waterloo, with that of Gravelotte, Sedan, and Plevna—that the losses have not become more severe. Distance fighting and the tendency to make greater use of the natural protection afforded by the lay of the land are factors that have led to decrease in actual mortality and to the infection of wounds that are not so serious as in the hand-to-hand combats that characterized the beginning of the century. These factors will play a still more important rôle in future wars and so make the position of the military surgeon ever more and more important.

"Water Dams in Mountain Regions," the third of the addresses at the first general session was not medical, but had a distinct interest for medical men because PROFESSOR INTZE of Aix proposed by the construction of huge reservoirs in mountain regions, first, to improve and enlarge the supply of drinking-water for cities and water for agricultural purposes; second, to retain the mountain population at home and prevent the present lamentable tendency to crowd into cities, by furnishing occupation to them in the employment in mills and factories of the water-power that might thus be harnessed; and third, to prevent the all too frequent suffering that is inflicted in various parts of the country by floods in the springtime, or after heavy rains in mountainous regions.

The General medical session was given up to papers on "The Physiology and Pathology of the Circulatory Apparatus."

PROFESSOR FREY of Zurich spoke of "Heart Activity and Its Physiological Relations." He supported the idea now becoming so popular that the heart-muscle acts automatically; that is, has within itself a potentiality to rhythmic contraction independent of nervous or circulatory connections. His comparison of ordinary striped, *i. e.*, skeletal muscle-fiber with heart-muscle was interesting in other regards also. Besides this capability of contraction apart from nervous connection, the heart-muscle fibers differ inasmuch as they virtually do not represent functional unities as do skeletal muscle-fibers. Heart-fibers

are so felted together and their branching network so connected that irritation of a single fiber is communicated to others and leads to the contraction of all. This does not happen with skeletal muscle-fibers, each of which is functionally independent.

Professor Frey sees in certain improvements in the technic of experimentation upon the heart great promises for the advancement of our knowledge of cardiac physiology and of the action of drugs upon the heart. Even the hearts of warm-blooded animals may now be kept beating for hours after removal from the body if proper precautions be taken. Recent experiments have shown that if but small quantities of blood or even serum be introduced at regular intervals into the coronary circulation and the heart kept constantly under a pressure of oxygen equal to about two atmospheres the hearts of warm-blooded animals may be kept alive even as long as twenty-four hours. The importance of this in our present insufficient knowledge of cardiac physiology and therapeutics is evident.

Professor Thoma of Magdeburg read a paper on "Affections of the Coats of the Blood-vessels as the Causes and Effects of Disturbances of the Circulation." He insisted especially upon the alterations in the walls of the capillaries, which are so early affected and which play so important a rôle in tissue metabolism. The capillaries must permit or influence the transmission of very different substances for nutritional purposes in the various tissues of the body, in the brain, for instance, in abdominal organs, in the bones, in the muscles. Slight alterations are sufficient to affect this delicate mechanism, hence the general nutrition suffers. This forms an important factor in all disturbances of the general metabolism.

"Processes in the Heart and Vascular System under Pathological Conditions" was the title of a paper by Professor Krehl of Jena, which, owing to the author's absence because of illness was read by Professor His of Jena. Professor Krehl considers that we do not as yet understand why under certain circumstances venesection does good. He has studied the effect of it on the various organs of animals. Its evident object would seem to be a reduction in blood-pressure, but this it accomplishes only for a while. There would seem to be alterative effects produced on general organic function by this passing reduction in blood-pressure that will yet form a groundwork for interesting studies. The other important element in cardiac pathology at present is the effect upon the heart of toxins, not alone those of bacterial origin, but those also due to defective organic metabolism.

In the Second General Session (combined medicine and general science) Professor Martins of Rostock spoke of "The Causes of and Predisposing Conditions for Disease." He considered that Virchow's address published in 1880 on "The Entity and Causes of Disease" is still and will remain one of the classics of medical literature despite the fact that it was published just before the present tidal wave of bacteriology had swept over the sea o modern medicine. The conclusions of Virchow's address remain practically as true to-day as twenty years ago, and though we have learned so much about the bacterial causes of disease, we are scarcely nearer to a satisfactory explanation of its real origin than we were before. What predisposition or tendency of the organism gives the opportunity for the vegetable parasite to gain a foothold we are no nearer knowing than before, yet this is *the* important element in the origin of disease. There was a time in the inception of modern pathological anatomy, when the discovery of the distinctive pathological lesion of the disease was thought to have brought medicine nearer to the *ens morbi*, to the essence of the disease. When it was found, for example, that hepatization of the lungs was characteristic of pneumonia it was considered that a distinct step had been made toward knowing the entity of inflammation of the lungs. Now we know the bacterial cause that sets up the hepatization, but we are no nearer knowing why one man is afflicted with it, another not, though both seem to have been exposed to similar conditions and in the mouths of both the pneumococcus may be demonstrable.

The cause of disease has always interested mankind, but words have displaced ideas only too often in the attempt to state it. Every practitioner knows that it is almost impossible to get clear, definite, satisfactory answers from most patients as to the preliminary symptoms, the course of the disease, and its effect on various functions, but all of them are ready to volunteer information as to its cause. One has taken cold, another has had rheumatism or has seen it in a friend, and has ascribed his symptoms to rheumatic trouble, or it is gout, etc. There is a widespread belief in the mysterious action of certain simple causes that directly attack the organism, the question of predisposition being left out of the question.

There is a feeling in this matter amounting almost to fetichism and which corresponds to that other almost universal feeling, that there are in Nature certain mysterious remedies that repair natural forces in the same simple direct way as the supposed pathogenic agents work harm. Nearly every physician has had the experience of asking educated people, members of the aristocracy even, why they gave recommendations to quacks, only to receive the naïve answer, that they thought in perfect good faith that the wonderful man had discovered secrets of Nature which had escaped the medical profession, and that these mysterious forces over which he alone had control are more powerful than disease.

Each step in modern medicine has brought us farther and farther from this simple naïve causal idea of the origin of disease and this simple specific therapeutics. If exposure to microbic infection was always followed by disease, then bacteriology would have given us an explanation of the origin of disease. Infection and disease are by no means correlative terms and the difficult question of susceptibility comes in as an important element to make us realize that we are still a long way from the explanation of specific pathogenesis. The study of this question of susceptibility and its causes is to be an important occupation for the pathologist of the Twentieth Century, and much more is to be hoped from a widening

of our knowledge of predisposing conditions to disease, than from the further discovery of specific bacterial causes. This advance in knowledge, however, will came from no one-sided bacteriological hygienist, but from those who have studied profoundly the conditions of disease as they are.

PROFESSOR VAN HOFF of Berlin spoke on "The Increasing Significance of Inorganic Chemistry." While for a number of years general attention has been directed to organic chemistry, of late a series of most important discoveries have recalled attention to inorganic chemistry. No less than six new elements have been found within a year or two, argon, helion, metargon, neon, krypton, xion; carborundum, calcium carbid, aluminium, chromium, and the rarer metals are being prepared commercially. The connection with physics, especially with the laws as to heat, are giving the theory of chemistry an impulse at the end of the century, such as it derived from the laws of atomic and molecular weights at the beginning of the century. In this new birth of the science from which so much was vainly hoped for medicine originally, there can scarcely fail to be great advantages for the sister science and especially for the cognate departments of physiological chemistry and pharmacology.

Overwork in the Schools.—Some of the sessions of certain sections were the scene of interesting discussions. The section for hygiene and the section for mathematical and scientific instruction each touched, though entirely independently and on different days, on the subject of overwork at school. The mathematicians and scientists demand that less time be given to the ancient languages, especially to Greek, and it was even suggested that Greek be dropped entirely in the preparatory schools. Practically all were agreed that too much work is demanded of pupils under the present system. Professor Pietzker of Nordhausen severely condemns the system of cramming for examinations. Professor Griesback of Mülhausen, in Alsace, condemns the examinations themselves. If a teacher does not know his pupils at the end of six or seven years, an hour of questioning them under the excitement of examinations will bring him no nearer such knowledge.

In the section for hygiene the question of school overwork came up in the discussion of Professor Kruse's (Bonn) paper on "Physical Degeneration and the Capability of Bearing Arms." Professor Bail of Prague claimed that the number of those exempted from military service because of physical defects is especially great among the one-year volunteers, that is, among those who because of a certain degree of education are excused from serving the full three years ordinarily required by law. The reason he considered to be overwork at school among this class. Professor Erb of Heidelberg had expressed himself in the same sense, especially as regards the development of neurasthenia in this class. General Arzt Stricker of Münster could not be sure that the Physical incapability of bearing arms was due especially in the educated classes to nervous diseases, but he had found hysteria and neurasthenia persistently on the increase among the men during their military service.

In the section on hygiene Professor Hankin of Agra, India, the government bacteriologist for the Central Department of India, was given a very enthusiastic reception. He spoke on "The Method of Dissemination of the Pest (Indian plague)." He considers it essentially a rat disease. In India years of careful observation have convinced him that the disease always originates among the rats, and that wherever successful means have been employed to drive out the rodents, the plague disappeared. Wherever the rats were most numerous the plague was worse. The surest prophylaxis against the plague would be in his opinion some sure method of getting rid of the rats.

This year the section for the history of medicine met independently for the first time and was very well attended by specialists. Körte, privat docent in archeology at Bonn, spoke on "Attic Gods of Healing and Their Places of Worship," with demonstrations from recent excavations by Dörpfeld. One very interesting bit of terra cotta found in the neighborhood of Veii was exhibited which was a sort of manikin and gave the positions of the organs of the human body. Its date is over 400 B. C.

In the section for history and also for veterinary medicine, the presentation of photographic copies of the well known papyrus of Kahun, which deals with veterinary medicine, attracted a great deal of attention. This is believed to be the oldest medical manuscript in existence.

SOCIETY PROCEEDINGS.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Abstract of the Proceedings of the Twenty-fourth Annual Meeting, Held at Nashville, Tenn., October 11, 12, 13, and 14, 1898.

FIRST DAY—MORNING SESSION.

THE Association met in the Hall of the House of Representatives at the State Capitol, and was called to order by the Chairman of the Committee of Arrangements, DR. DUNCAN EVE. Prayer was offered by REV. JAMES I. VANCE, D.D. Addresses of Welcome were delivered by HON. J. M. HEAD, on behalf of the city and State, and by DR. C. S. BRIGGS, on behalf of the profession of Nashville.

After the reading of the reports of the Secretary and Treasurer, which were accepted, the President's Address was delivered by DR. JOHN YOUNG BROWN of St. Louis, Mo. He selected for his subject

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

He dealt with the history of the Association, saying that it was organized twenty-four years ago. Its rapid growth is due to the loyalty of its members and to the fact that from its inception it has been a distinctively working body. It has never been a mutual-admiration society. He made suggestions for its improvement, and said that inasmuch as the Association contemplates the publication of an an-

nual volume of Transactions, he would suggest that the dues be raised from $3 to $5.

Dr. Charles T. McClintock of Detroit, Mich., read the first paper, which was entitled

IMMUNITY.

Of late years a large part of the laboratory work in medicine has had to do with immunity. Many facts have been discovered; in a few instances these have been of immediate practical value in the treatment or prevention of disease. But, for the most part, these facts are uncorrelated, often contradictory, their meaning not clear. Hypotheses have been advanced, but as yet we have no theory that will even approximately explain the facts of immunity. The future of work in this line is full of promise. For the infectious diseases at least, immunity and cure are one and the same. A diphtheria patient will be cured only when its tissues are immunized against the attack of the diphtheria poison. There are several kinds and various degrees of immunity. We have a natural and an artificial or acquired immunity; apparently these are entirely different in kind, dependent on different functions of the body, effected by different substances. There is racial immunity. Again we have an immunity correlated with age. Variations in susceptibility are noted in different varieties of the same species and in different families.

Again, there is an individual immunity. Still again, one part of the body, even one portion of the same tissue, may be immune, while the rest is very susceptible. These facts are not to be explained by general resistance, good health, etc. The most vigorous man may acquire smallpox or influenza. The healthiest cow is likely to take pleuropneumonia.

Metschnikoff's theory (phagocytic) is the best explanation we have for natural immunity. Nuclein seems to be the germicidal agent elaborated by the white corpuscle. If natural immunity is due to one or several chemical agents, it follows that it is limited. Chemical action is always greater to life. After recovery from certain infectious diseases there is more or less of immunity to that disease. In some instances, as in scarlet fever or syphilis, this acquired immunity usually lasts for life. The immunity following recovery from disease is not proportional to the intensity of the disease process. The ability of an organism to resist the attack of disease germs or their products can be increased, trained, educated, if you will. Thus, in producing diphtheria antitoxin, we often get our horses to bear without apparent harm several thousand times the fatal dose of poison for an untreated horse. It may happen that diphtheria or measles may after generations or centuries disappear, owing to the fact that the race becomes immune.

To what extent an acquired immunity can be inherited is both an interesting and important question. This sort of immunity is usually lost, at least so far as our tests will show, before the animal reaches the adult stage. This inherited immunity is not the same as the immunity of the suckling. This is due to the fact that the immunizing bodies pass into the milk. The child receives from its mother not only food, but disease resisting power. There are active and passive forms of acquired immunity. The horse producing antitoxin is actively immune; his tissues are producing antitoxin. The child receiving a dose of antitoxin is passively immune. It has borrowed the strength of the horse.

There is an immunity to poisons. The wolf thrives on putrid flesh. Some animals are immune to snake poison. The insusceptibility of the morphin user may be something more than mere tolerance. The drug may be in part destroyed, and this anti-power may have to do with the craving for the drug.

There is no satisfactory explanation for the facts of acquired immunity. The various theories as to the nature of antitoxin and its mode of action were given, with the conclusion that antitoxin, in some way as yet unknown, stimulates some portion of the body, and this in turn destroys the poison. There is no antitoxin, but, in short, an immunizing body. Immunity and cure are the same thing.

Dr. George W. Johnson of Dunning, Ill., had had some experience with nucleinic acid in the treatment of pulmonary tuberculosis in cases of mixed infection, and had noticed a diminution in the number of pyogenic bacteria, and asked whether the phagocyte attacks the tubercle bacillus the same as it does pyogenic bacteria.

Dr. McClintock replied that he knew of no reliable investigations that have been made with reference to that point.

Dr. Ernest B. Sangree of Nashville said it is believed by many investigators that the phagocytes eat live tubercle bacilli, and that cases in which tubercle bacilli are included in the phagocytes have a better chance to get well than those which do not contain them.

Dr. Dudley S. Reynolds of Louisville was afraid that experimental observers have failed to note the necessary equilibrium between the circulating blood current and the lymph stream. Dr. Reynolds elaborated the theory of phagocytosis and showed how phagocytosis can never be successful if obstructions exist in the lymph-channels.

HYGIENE VERSUS DRUGS IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

Dr. C. L. Minor of Asheville, N. C., read this paper. Under hygienic and dietetic treatment the author embraced all such non-medicinal measures as are directed toward an increase in the vitality of the organism, and of its resistance to disease, and remarked that climatotherapy is but a branch of hygienic treatment, although he did not embrace it in his remarks, which were confined to the proper application to individual cases of exercise, gymnastics, massage, hydrotherapy, rest, sleep, diet, amusements, clothing, and quarters. A partial and unsatisfactory use of such measures is more or less general, but unless directions be definite and specific, they will fail of their purpose. The difficulty of getting a patient to yield implicit obedience to the doctor was dwelt on, the indefiniteness of the orders given being in part to blame. If he is to recover, the patient and doctor must both work hard, no half-hearted seekers for pulmonary

health being likely to recover. The necessity of carefully and fully writing out exact orders for every detail of the patient's life, to be followed religiously by him, was urged, such a prescription being in phthisis of more value than the more common one for drugs. All such measures were for convenience classed under three heads: Those affecting the patient's surroundings, his life, and his exercise.

The very common abuse of exercise was deplored, and the invariable rule stated, "exercise short of the point of fatigue," and the other of "no exercise with a temperature over 100.4° F.," following which no mistake can be made.

A very gradual accustoming of the patient to longer and longer walks, beginning with only fifty or a hundred yards in many cases, and increasing until finally from two to ten miles can often be easily tolerated and a judicious use later on of walks on increasing incline, till steep hills are easily surmounted, was warmly recommended. Pulmonary gymnastics was most especially dwelt upon for use in non-active cases, and among several methods recommended for chest development and the increase of vital capacity, that form of Indian club swinging called the double figure-of-eight was chiefly recommended. Finally, any intention to advocate nihilism in medicine was denied. In carefully selected cases certain drugs have undoubted value as adjuvants, never as the chief resource. The short life of most drugs in phthiso-therapy was noted, and ascribed to the fact that no man can treat this disease long and not realize that nothing that in the least degree upsets the stomach can be anything but a curse to the patient. The only valuable results are those based on a vitalizing of the whole system, a stimulation of metabolism on a strengthening of the cells to oppose the invader. The thing to be attacked is not so much the lesion in the lung directly as the lowered vitality of the body, the diminished capacity of the lungs, and the deficiency of appetite, and drugs directed to a conquering of the bacillus *in situ*, are not to be compared with measures which enable the organism itself to acquire the strength to overcome disease. These things can be brought about best by an improvement in nutrition, which must after all come from the stomach, and an increase of the amount of oxygen taken into the lungs. Air and food: These are the drugs to which we can always trust; they will never deceive us, if a patient can be taught to get both in good amounts whenever food can be assimilated and enjoyed and air breathed deeply, there is hope of cure. Throw away two-thirds of our medicine bottles and use the other third less often, carry out a hygienic plan of life, stimulate the appetite by Nature's appetizers—air and exercise—which are alone permanent in their results, and which are as superior to gentian or quassia as sunlight is to darkness.

DR. S. C. BALDWIN of Salt Lake City, Utah, contributed a paper on

CONGENITAL SCOLIOSIS.

Scoliosis is (1) the most common of all deformities. (2) It is most often found in children under ten, rarely beginning after eighteen. (3) It is found more often in girls in the ratio of five to one. (4) The etiology is in a large number of cases very uncertain. Congenital scoliosis is very rare. Tubley of London, in the latest English work on deformities, says that he has been able to verify only four cases.

The case reported by the essayist was first diagnosed as scoliosis when the child was twenty-one months old, but the father had noticed the "lump" ever since the child was first washed. The interesting features of the case were that the curvature was in the lower cervical and upper dorsal region. There was some pressure on the cord, as shown by the more or less deficient development of the right side. The convexity of the curve in this case was to the left. There was partial paralysis of the forefinger of the right hand. There was sweating and flushing of the left side but none on the right.

The cause of the scoliosis in this case was thought to be the lack of amniotic fluid while in utero, probably allowing the muscular walls of the uterus to press on the fetus and hold it in a faulty position, and in this way cause a wedge-shaped development of the bodies of the vertebræ. This theory has been advanced by Weissenberg, Hirsh, and Schauz in the last year. In this case the mother was very small, and passed at the time of confinement so little water that she did not know there was any, and felt no motion comparatively during pregnancy.

DR. SAMUEL E. MILLIKEN of Dallas, Texas, had seen one case of scoliosis in a child under one year of age, but was not prepared to say whether it was congenital or not.

AFTERNOON SESSION.

DR. WILLIAM L. BAUM of Chicago read a paper on

THE THERAPEUTIC VALUE OF MARMOREK'S SERUM.

He dealt with the literature of the subject in an exhaustive manner. Twenty-two cases have come under his observation in which the serum was used. Of these, 19 were cases of erysipelas; 1 of erysipelas plus tubercular nuchal glands; one of facial erysipelas during child-bed without septicemia, and 1 of erysipelas with puerperal septicemia and double labial abscess. The last was the only fatal case. The serum used was supplied by Parke, Davis & Co.

The deductions he draws from an analysis of the literature and his own experience are: (1) In pure streptococcic infections the serum undoubtedly exercises a favorable influence on the course of the disease. (2) In the mixed infections the influence of the serum is noticeably demonstrable, but it merits further trial as an adjunct to other treatment. (3) Considering the grave character of the complications of a non-streptococcic nature reported, ordinary rules of therapeutics demand that in such cases, as with the diphtheria antitoxin, all indicated therapeutic procedures must be employed as well as the serum. (4) In view of the fact that erysipelas streptococci and phagocytes have been found to exist side by side in the lymph channels, it is fair to assume that the influence of the serum is directly exerted bacteriologically on the streptococci and not entirely through stimulation of phagocytic action. (5) The initial dose in all cases should be 20

c.c., to be followed by 10 or 15 c.c., according to the indications, every twenty-four hours.

Dr. Charles L. Minor said his experience had been practically confined to secondary infections in tuberculosis. He had used the serum of Parke, Davis & Co. with considerable satisfaction in preference to Marmorek's.

Dr. Samuel E. Milliken had used antistreptococcic serum in two cases, both of which terminated fatally. One was a case of abscess of the liver, the other a suppurative appendicitis.

Dr. William K. Jaques of Chicago called attention to infections in the pulmonary tract that he has found to be purely streptococcic, and in such cases he has advised injections of antistreptococcic serum with good results.

Dr. Baum, in closing, emphasized the importance of diagnosing the kind of infection present.

Dr. Albert Bernheim of Paducah, Kentucky, presented a paper and reported three cases of syphilis in which he administered blue ointment by the mouth with satisfactory results. He urged a thorough trial of this method, believing it will please the patient as well as the physician. The method of administering blue ointment by inunction is disliked by the patient on account of its nastiness and inconvenience, hence if another method of using the ointment can be substituted with the same good and quick results, why not adopt it?

Dr. James T. Whittaker of Cincinnati delivered the address on medicine. He selected for his subject

DIABETES MELLITUS.

Dr. Andrew Timberman followed with a paper, entitled

MASTOIDITIS; WHEN TO OPERATE AND HOW.

The cause and symptoms of this affection were described. To know when to operate one must be able to exclude the diseases which are often accompanied by inflammatory conditions over the mastoid without actual involvement of the bone, and which quickly recede when the primary disease is properly combatted. Every physician in his experience sees cases of simple furunculosis, and diffuse external otitis presenting as marked symptoms as painful and swollen mastoids. The tissues are boggy and the edematous condition is determined by palpation, pain, and pressure. Such diseases, as well as syphilis, must always be excluded as a *sine qua non* before operating.

He divided cases of mastoiditis into two classes, the first comprising those complicating acute aural disease; the second class, those complicating chronic aural affections. This division ignores primary mastoiditis, which is very infrequent.

Conclusions.—Operative measures should be instituted: (1) to preserve the function of hearing as well as to prevent a fatal issue; (2) earlier in mastoiditis due to scarlet fever, diphtheria, and the worst cases of influenza than when due to cold, measles, typhoid fever, etc.; (3) in the acute cases of mild infection, when subsidence does not occur within at most eight days (Schwartze). A shorter period is safer in a virulent infection. (4) Recurrent mastoiditis due to any cause. (5) In mastoiditis complicating a chronic suppurative otitis. (6) In acute cases when there is a drooping of the lining membrane of the superior posterior wall of the external auditory canal, carrying with it the membrana Shrapnelli; in chronic cases when at the same place a crater-like opening leads to the recessus epitympanicus and auditus ad antrum, even though in neither case symptoms immediately menacing life be present.

The author favors the typical or original Schwartze method of opening the mastoid antrum. Its success in given conditions justifies its application; its failure in given conditions has resulted in a more perfect procedure styled the Schwartze-Stacke or radical operation.

Dr. J. Homer Coulter of Chicago maintained that the general practitioner should not treat cases of mastoiditis in which the symptoms are well defined, and no one who has not had considerable surgical experience should attempt the Schwartze operation.

Dr. J. A. Stucky of Lexington said that in many cases of necrosis of the malleus he has made a free incision along the posterior-superior wall of the canal, curetted the diseased bone away, tamponed the canal lightly with iodoform gauze, and patients have done well without undergoing the radical operation.

Dr. Dudley S. Reynolds laid stress on the importance of instituting constitutional medication in the stage of invasion in cases of mastoiditis, saying that an ounce of prevention at this time is most preciously bestowed.

Dr. L. B. Graddy of Nashville called attention to a point not mentioned in the paper—the differential diagnosis between mastoiditis and mastoid periostitis. If cases are carefully observed there is as much difference between the two conditions as there is between a periostitis of the tibia and an epiphysitis. This differentiation is of paramount importance in the treatment, whether it be medical or surgical.

PROPHYLAXIS IN NOSE AND THROAT DISEASES.

Dr. J. Homer Coulter of Chicago read a paper on this subject. He said that there are many preventable pathological conditions in the nose and throat, and that many of the ordinary diseases of this portion of the anatomy have evoluted into more serious and distinctly different affections will be admitted without question. He omitted any reference to such conditions as syphilis, tuberculosis, diphtheria, influenza, or the exanthemata, inasmuch as the possible prophylaxis in each affection is a matter of general knowledge. He also omitted reference to any technical details which are at best mooted points with authorities.

Surgery does not cure all conditions, nor does it even prove always a prophylactic blessing. So also do local applications and constitutional treatment prove unavailing if universally depended upon. This is due in a measure to the lack of carefully exacting and eliminative diagnosis. With the development of our knowledge of the physiology of the nose and throat have come also new ideas of the connection between many diseases of those

organs and of their relative etiological importance. The impairment to ventilation and drainage is a most important factor, and one usually amenable to surgical treatment. "Taking cold" is not only a most frequent condition, but one the most susceptible to prophylactic measures. Clothing of the entire body is a factor of paramount importance in prophylaxis. Too much clothing about the head and neck is just as disastrous as insufficient protection. Adenoids, polypi, spurs, exostoses, deviations, deflections, and sensitive areas are each amenable to surgical treatment and demand such interference as soon as recognized. On the other hand too much surgery is quite as disastrous as too much conservatism. The tonsils are the cause of other and reflex pathological conditions as frequently as are adenoids. Mouth-breathing should be recognized as a most significant danger signal.

Conclusions.—Anything which produces an alteration in the normal physiological metabolism of the mucous membrane of the nose and throat; any alteration in the nutrition of the parts, any abnormal variation in functional activity; any considerable change in the histological anatomy are each and all remedial surgically or otherwise and are therefore amenable to prophylactic efforts.

DR. A. J. STUCKY of Lexington followed with a paper, entitled

PERITONSILLITIS OR QUINSY; CAUSE AND TREATMENT.

Of ten authors consulted seven after citing hereditary predisposition, exposure, etc., mention rheumatism and gout as the most prolific causes of this malady. Close observation and careful testing in selected cases convinces him that the rheumatic, or more probably the uric-acid diathesis, has more to do with the causation of this disease than any other factor.

Coming to the treatment he believes if the majority of cases of quinsy are seen within forty-eight hours after the first onset of the disease, they can be aborted to such an extent that suppuration will not take place. In cases that progress to suppuration, he strongly advocates early and free puncture, just as soon as there is marked distention, in order to relieve pain and stop the destructive suppurative process. For this purpose he uses a modification of an ear spoon, first described by Spier, and not a knife.

(To be continued.)

REVIEWS.

TRANSACTIONS OF THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. Vol. X. Published by the Association, 1898.

THIS volume, a record of the meeting held in St. Louis in November, 1897, contains the usual number of interesting papers. The improvement of surgical technics and a discussion of extra-uterine pregnancy are salient features. Judging from this report the meeting must have been an unusually interesting one.

THERAPEUTIC HINTS.

For the Coughing Spells of Phthisis.—

℞	Bromoformi	gtt. xxx
	Ext. opii	gr. ii
	Spiritus	ʒ iiss
	Syr. ipecacuanhæ	℥ i
	Aq. laurocerasi	ʒ v
	Syr. simplicis	℥ v.

M. Sig. Three or four tablespoonfuls in twenty-four hours.

For Tapeworm.—After purgation by means of castor oil or sulphate of magnesia, administer the following mixture:

℞	Spts. chloroformi	ʒ ii
	Ol. terebinthinæ, Oleoresinæ aspidii aa.	ʒ i
	Glycerini	℥ ss.

M. Sig. Two teaspoonfuls every hour for four or six hours.

Symptomatic Treatment of Arteriosclerosis.—

1. For vertigo:

℞	Potassii iodi	gr. lxxx
	Potassii bromidi	ʒ iiss
	Sodii arsenitis	gr. 1⅔
	Aq. dest.	℥ x.

M. Sig. Two tablespoonfuls a day.

2. Diuretic for nocturnal dyspnea:

℞	Ext. grindeliæ fl.	℥ i
	Tinct. convallariæ	ʒ iiss
	Tinct. scillæ	*m.* lxxx.

M. Sig. Fifteen drops three times a day.

3. For palpitation:

℞	Tinct. digitalis, Tinct scillæ, Tinct. aconiti aa	ʒ ii.

M. Sig. Ten drops three or four times daily for eight or ten days.

4. For cardiac weakness due to errors in diet, etc.:

℞	Sparteini sulphat.	gr. viii
	Sodii iodi	gr. lxxx
	Aq. dest.	℥ iii.

M. Sig. One teaspoonful twice a day.

Treatment of Scarlatinal Nephritis.—HURWITZ reports a case in a child of seven, in which, after all other treatment had proved ineffectual, a rapid and complete cure was produced by bleeding to the amount of about six ounces. The edema disappeared on the following day.

Formula for a Dental Soap.—

℞	Thymol	Parts 5
	Extr. krameriæ	" 20
	Glycerini	" 120
	Magnesiæ	" 10
	Sodii borat.	" 80
	Ol. menthæ pip.	" 20
	Saponis med.	" 600

Dissolve the thymol and krameria in the glycerin (hot), then add the other constituents, stirring constantly.

CARBONIC-ACID GAS; ITS PHYSIOLOGICAL ACTION AND THERAPEUTIC EFFECT, AS SEEN IN EMPHYSEMA OF THE LUNGS, ANEMIA, WHOOPING-COUGH, DYSENTERY, AND IMPOTENCE.

BY A. ROSE, M.D.,
OF NEW YORK.

1. *The Physiology and Chemistry of Respiration.*—Carbonic acid is a constant constituent of the animal organism. The minor portion of the carbonic acid is obtained from the atmosphere and nutriments, the major part from the tissues and blood, forming one of the most important end-products of oxidation and tissue metamorphosis. It develops the effects of a weak acid, and like alcohol, those of an excitant and paralyzing agent. It enters the blood through the capillary circulation from the tissues in which it is formed. The gases occurring in the blood under physiologic circumstances are oxygen, carbonic acid, and nitrogen. The latter is present only in minute quantities and seems to play no important rôle in the vital processes, its quantity in different parts of the circulation being approximately the same. The amounts of oxygen and carbonic acid in the blood derived from various parts of the circulation differ in accordance with the rapidity of the blood current, different temperature, rest and labor, etc. Oxygen is contained in the arterial blood of man, according to Setschenow, to the amount of 21.6 per cent. by volume. Ludwig and Szeltcow found 6.8 per cent. of oxygen by volume in the venous blood of non-active muscles, and still smaller quantities in that of those in action. Oxygen is entirely absent, or present only in traces, in the blood of the asphyxiated. Zuntz states that the venous blood of the right heart contains on an average 7.15 per cent. less of oxygen than the arterial blood.

The quantity of carbonic acid contained in the arterial blood is usually 40 per cent. by volume and varies between 30 and 40 per cent.; it always corresponds exactly or very nearly so to the amount contained in the air of the alveoli. Every change in the composition of the alveolar air must be followed by a corresponding change in the tension and the absolute quantity of the carbonic acid in the arterial blood. Again, the carbonic-acid tension of the arterial blood affects primarily the diffusion between the blood and the tissues; hence, any variation in the proportion of carbonic acid in the alveolar air, continuing for some time, will cause a corresponding change in the proportion of the carbonic acid of the blood and tissues. The proportion of carbonic acid contained in the venous blood varies still more. According to Zuntz's calculation, the venous blood of the right heart contains 8.2 per cent. of carbonic acid more than the arterial blood. The average quantity is about 40 volume per cent. In the blood of the asphyxiated, Holmgren found even 69.21 volume per cent. of carbonic acid.

Almost all the oxygen in the blood is loosely held by the oxyhemoglobin, and only a small portion, 0.26 per cent., is absorbed by the plasma or serum. The circulating blood does not appear to carry oxygen entirely up to the point of saturation. Of the carbonic acid found in the blood the smaller portion, according to the examinations of Alex. Schmidt, Zuntz, and L. Frederiks, about one-third, is contained in the blood-corpuscles, but by far the larger quantity is carried by the plasma and serum. The carbonic acid in the blood-corpuscles forms a loose chemical union, firstly with the alkalies which there enter into combination with phosphoric acid, oxyhemoglobin or hemoglobin and globulin, and secondly with hemoglobin itself. In the presence of a preponderance or of a greater partial pressure of carbonic acid, the relations of the alkali compounds to carbonic acid undergo changes. Hemoglobin possesses the ability to absorb the two gases, oxygen and carbonic acid, independently of each other and simultaneously. The major amount of carbonic acid in the blood is found in the plasma or serum; it is more abundant in the serum than in the blood itself. One part is simply absorbed, the larger part is in loose, and the smallest part in firmer chemical union; the quantity which is simply absorbed could not be exactly determined. Setschenow estimates that in the serum of the dog it forms about one-tenth of the entire carbonic acid contained in the blood.

The quantity of carbonic acid in firm chemical combination must be determined by the amount of alkali-carbonates. It is, however, not exactly known, inasmuch as the alkalies of the blood are not only associated with carbonic acid, but also with other components, especially with the albumins. The amount of the carbonic acid in the blood corre-

sponds with the amount of alkali. Such, for instance, is the case when poisoning with mineral acid takes place. Thus Walter found only 2 to 3 volume per cent. of carbonic acid in the blood of rabbits, into the stomach of which he had introduced muriatic acid. The oxygen of the blood exists in dissociable combination with the hemoglobin, and this combination, the oxyhemoglobinic, depends on a certain partial pressure of the oxygen, varying with varying temperature. The same is the case with carbonic acid in blood, that contained in the corpuscles as well as that in the plasma; it exists there in combinations which depend to a high degree on partial pressure.

Quite a number of elements act together with carbonic acid, making it apparently impossible to decide the quantitative part of each single factor in the entire effect.

It is of great importance to know the amount of tension of oxygen and carbonic acid in the blood in order to decide the question of the exchange of gases between the blood and the alveolar air on the one hand, and the blood and the tissues on the other; especially to decide in how far this exchange of gases takes place under the laws of diffusion and in how far, also, other forces may be active. The change of gases in the tissue, the so-called internal breathing, takes place in the following manner: oxygen leaves the capillaries to enter into the tissues and simultaneously the main mass of the carbonic acid of the blood which originates from the tissues, leaves the latter and enters into the capillaries. The change of blood in the lungs, the so-called external breathing, is the taking up of oxygen by the blood from the air in the lungs, and giving up of carbonic acid into the latter. These processes of the double gas exchange are not yet sufficiently explained. The question which is yet to be solved is: does the exchange of these gases take place in consequence of the difference between their tensions in the blood and in the air in the lungs, by the laws of diffusion, or are there other factors active?

At present we cannot produce sufficient reasons for abandoning the view generally adopted, that the entrance of oxygen into the lungs takes place simply by means of diffusion; and further, that the amount of oxygen in the blood—within certain limits—does not especially depend on the amount of oxygen in the atmospheric air. Indeed, it is known that the increase of the oxygen pressure, even to the strength of one atmosphere, has no essential influence on the amount of oxygen taken into the lungs and the amount of carbonic acid which is exhaled. Animals placed in pure oxygen under a pressure of three atmospheres suffer convulsions and perish quickly. This oxygen intoxication is characterized by extraordinary reduction of consumption of oxygen. All organisms, animal as well as vegetable, succumb alike. Oxygen exerts a deleterious effect in the different organisms when they are exposed to it for a greater length of time, even at a tension far below the one which kills quickly.

When we inhale pure oxygen its consumption and the formation of carbonic acid become diminished. The deleterious effect of excess of oxygen and over-accumulation of carbonic acid when working together cause an animal to perish even when neither of the two gases by itself is present to a dangerous degree. Although carbonic acid is excretory matter, and life can only be continued when this gas is eliminated from the system regularly by rhythmically returning respiration, it would be erroneous to deny it all further rôle in the economy of the system. The carbonic acid in our organism with its normal quantitative changes seems to be necessary to excite important vital functions, especially respiration and circulation. The symptoms of intoxication when excessive quantities of the gas have been inhaled, may be explained, to some extent, as exaggerations of normal physiologic processes.

Concerning the elimination of carbonic gas in the lungs we are still without reasons for abandoning the generally adopted view according to which the carbonic-acid gas coming from the blood enters the lungs simply by the law of diffusion. There is a considerable difference between the pressure of the oxygen in the blood and the oxygen in the tissues, and owing to this difference of pressure the tissues are supplied with the necessary amount of oxygen. Quite the opposite is the case with carbonic acid; its tension is higher in the tissues than in the blood, and all the investigations thus far made have produced no evidence against the assumption that carbonic acid from the tissues enters the blood simply by the laws of diffusion.

Considering even superficially the quantities of oxygen in the blood it appears at once plain enough that the main amount cannot have been absorbed physically, for the serum of the blood, as a solution of indifferent substances, absorbs less oxygen than pure water—it can absorb 0.3 volume per cent. of oxygen from the atmospheric air at the ordinary temperature of the body. In reality, however, arterial blood holds not less than seventy times this quantity of oxygen. The same applies to carbonic acid, the largest part of which, as has been shown, is held in chemical union in the blood and cannot to any great extent be absorbed physically. The partial pressure of the carbonic acid in the blood is much too small to allow the gas to be simply absorbed.

The comparison of the gases of the arteries with those of the veins is of great importance because it furnishes directly the evidence that real processes of combination do not occur to a considerable extent in the lungs, but almost the whole amount of oxygen which has entered the lungs can be separated from the blood of the arteries by means of the exhaust-pump.

The mass of inspired air has to be divided in regard to its action on the renewing of the air in the alveoli into two parts. A certain amount remains in the upper air passages and is removed again by expiration; the rest enters into the alveoli to mix with the air which is there already; on account of the smallness of each single infundibulum it is likely that the diffuse mixture of old and fresh air takes place momentaneously while the bronchial tubes are too long to allow the exchange of their gases with those of the alveoli by diffusion, which certainly could hardly be accomplished in the time between two respirations. The next process in respiration is that air from the alveoli takes the place of the expired contents of the bronchi, and only when the extent of the expiration exceeds in volume that of the air-passage, alveolar air will pass out directly. The movements of respiration, therefore, can have but little success when the volume of each expiration does not exceed that of the air-passages; that is, does not more than exhaust the contents of the air-passage. Thus, a very superficial breathing will only insufficiently ventilate the alveoli, even when the frequency of respiration is increased. The expired air is the richer in carbonic acid and the poorer in oxygen; the larger part of it comes from the alveoli, that is, the more profound the expiration.

2. *Inflation of the Large Intestine with Carbonic-Acid Gas for Diagnostic Purposes.*—H. v. Ziemssen was the first who, in the year 1883, described and published experiments to establish the value for diagnostic purposes of artificial inflation of the large intestine. His method is to develop the gas within the intestine by introducing through a rectal tube, first bicarbonate of soda, then water, and finally tartaric acid. Rosenbach has published the results of a large number of experiments made on the living subject and also on the cadaver by inflating the large intestine with liquefied carbonic acid. The selection of liquefied carbonic acid in place of the effervescent mixture offers a number of advantages: (1) it allows an exact dosage; (2) the induction of the gas is absolutely uniform and constant; (3) the inflation may be interrupted at any desired moment, and be continued again at will, and for this reason much larger quantities of gas may be introduced; (4) there is no liquid applied together with the gas; (5) the pressure under which the gas enters is a much higher one; (6) there is no apprehension of accidents which are apt to happen when the two components for the development of the gas are introduced separately.

The carbonic-acid gas is taken from an iron reservoir, in which it is contained in the liquefied form; a double stop-cock is attached to regulate exactly the flow of the gas from the container, where it is, naturally enough, under high pressure. The carbonic acid in escaping from the reservoir at once assumes the gaseous form. From the reservoir it passes first into a bottle filled with water. This is for the purpose of enabling one to observe and to control the celerity of its escape. From this bottle it enters into an elastic tube with a nozzle for the rectum at the end. The nozzle having been inserted into the rectum the stop-cock is opened to such a limited extent that one is enabled to count the gas-bubbles passing through the water. A few seconds after the gas enters the rectum there is produced a sensation of warmth, then a slight desire to evacuate the bowel, which immediately passes away. In patients who avoid pressure and control the levator there is no voiding of gas, the muscular closure sufficing to retain it; in some cases it is advisable to secure closure by means of a rubber valve fastened to the rectal tube, which valve is pressed against the anal opening. If even this means should fail to securely close the opening one may simply increase the amount of gas entering by opening the stop-cock somewhat wider; then while more gas enters than escapes, a satisfactory filling up of the intestine takes place. The abdomen gradually becomes expanded and when the patient commences to complain of tension the induction is discontinued. It is well to inflate an empty rectum in order to avoid obstruction of the tube by fecal masses. The amount of gas entering the intestine may be measured; for practical purposes, however, it is of no importance to know the exact amount.

Rosenbach has given a very thorough and exact description of the behavior of the intestinal tract when inflated with carbonic-acid gas and his observations are of great value for diagnostic purposes. They are of great importance to us in so far as they furnish conclusive evidence that carbonic-acid gas may be employed with perfect impunity. When the inflation is carried out *ad maximum* the lower part of the abdomen becomes expanded, the abdominal walls are under great tension, but notwithstanding the liver is not at all or only very slightly pushed upward; on percussion over this organ the dulness remains about as before; there is no raising

of the diaphragm, and consequently no retraction of the lungs; no dyspnea is observed; no cyanosis. Persons experimented on may complain of disagreeable tension of the abdominal walls, but even this unpleasantness disappears more and more as the patient becomes accustomed to inflation.

Rosenbach's experiments confirm the well-known fact that we cannot, by way of the rectum, inflate the small intestine; especially conclusive in this regard are his experiments on the cadaver. The inflation cannot be carried out beyond a certain limit, which limit corresponds exactly to that noticed in the living. In attempting to force induction beyond this limit he did not succeed; gas would escape through the anus or it would find such strong resistance that no more could enter. He carefully opened the abdominal wall without injuring the intestine and was able to convince himself that notwithstanding the considerable meteorism the inflation did not extend beyond the ileocecal valve.

(To be continued.)

XEROSTOMIA, OR DRY MOUTH; REPORT OF A CASE.

By AUGUST JEROME LARTIGAU, M.D.,
OF ALBANY, N. Y.;
ASSISTANT IN PATHOLOGY AND BACTERIOLOGY IN THE BENDER HYGIENIC LABORATORY; LECTURER ON CLINICAL MICROSCOPY IN THE ALBANY MEDICAL COLLEGE.

In 1888 Mr. Jonathan Hutchinson and Dr. Hadden, before the Clinical Society of London[1] called attention to the peculiar condition known as xerostomia, and each reported a number of instances of this very infrequent and little known affection. Several other cases of the disease were also mentioned at the same meeting by other members of the society. Some conception of its rarity may be formed from the meager number of references which I have been able to find in medical literature. Dr. Thomas Harris[2] of Manchester, England, in a very recently published paper upon this subject was not able to collect reports of more than twelve cases. But in looking over the literature I have been able to find reports of several other cases which either had escaped Dr. Harris' notice, or have been published subsequently to his paper, making the total number of cases less than two dozen in all.

The following case came under my notice some years ago. In addition to the usual clinical presentation of such cases, the patient presented symptoms of a very striking and very unusual order:

E. L., widower, sixty-four years of age, came under my observation on January 20, 1895, complaining of marked dryness of the mouth and a very painful condition of the tongue. His father died of pneumonia at the age of fifty-one years, his mother of Bright's disease, aged forty-seven. Two brothers were living and healthy. Two sisters were living, both highly nervous women, one the subject of *crises nerveuses*, as the patient expressed it. The other sister had been the subject of violent periodical headaches for years. There was no history of ordinary diseases of childhood, chorea, pneumonia, malarial or typhoid fever. The patient denied luetic or other venereal infection. He had always been of a markedly nervous disposition.

The dryness of the mouth came on about five months before coming under observation, and about six weeks after the tragic death of his wife. Its onset was insidious and it was only when the condition became well marked that the patient's attention was seriously called to his affliction.

At the time of the first examination the following note was made: "Mr. L. is a sparely nourished, extremely nervous man; skin is quite dry; mucous membrane of lips and eyelids pale; pupils normal, conjunctivæ moist; lips dry and slightly fissured. Tongue is dry, moderately fissured, and covered with grayish-brown sordes. Mucous membrane of mouth dry, but otherwise quite normal in appearance. Pharynx is likewise dry; tonsils are somewhat enlarged; teeth are in fairly good condition. The parotid, sublingual, and submaxillary glands are normal in size, and the patient denies the existence of any enlargement of these glands at any time. Cervical glands not enlarged. The acuity of the sense of taste is somewhat diminished."

Salivary papillæ were not prominent. The mucous membrane of the nose had been normal, as was also the sense of smell. The heart, lungs, liver, and spleen gave no apparent evidence of functional or organic abnormality. The urine contained a trace of albumin and some hyaline and granular casts. Repeated examinations for sugar were made, but always with a negative result. Several examinations of the blood showed a very slight secondary anemia.

The degree of the mouth dryness was at all times considerable—enough to cause marked discomfort, and so much so at times as to become intolerable. These fluctuations of intensity were very appreciable subjectively, the patient stating that the dryness was less marked during the cold, moist season; in hot, dry weather, on the other hand, there was a distinct diminution of the salivary secretion, with the resulting more marked dryness of the mouth.

The skin was markedly less active than previous to the onset of the trouble, prior to which time the patient perspired on the slightest provocation, but since the disturbance perspiration ordinarily was no longer excited except on considerable and prolonged physical exertion. Furthermore he had observed that an improvement in the salivary function was accompanied by a slight corresponding amelioration of the cutaneous perturbation, and the more marked the improvement of the former, the more evident the closer return to the normal of the latter. Objectively, at no time had there been any apparent sensory or motor disturbances of any kind whatsoever.

Diet had been largely limited to liquid and semi-solid food.

From the time of my first examination in 1895 until July, 1898, the patient followed a number of treatments of various nature, with varying success. Iron, iodid of potassium, various salts of arsenic, mercury, and pilocarpus in different forms have been administered. Electricity was also used for a considerable length of time, and treatment by suggestion was attempted, but with no better success than with electricity. For a time during an aggravated period of the affection the pilocarpus relieved the dryness, but soon the efficacy of this remedy was lost. Arsenic similarly proved useful for a comparatively short time. At the present time the patient is in about the same condition that he was when first seen about three and one-half years ago.

The clinical ensemble of xerostomia is a fairly constant entity, as exemplified by the majority of the reported cases, which in a general manner have a more or less evident resemblance to each other as regards symptomatology and prognostic termination. The arrest of the salivary secretion and the resulting dryness of the mouth are, *par excellence*, the preeminent symptoms of this malady. The greatly restricted, or complete cessation of the salivary flow not only involves the parotid, submaxillary, and sublingual glands, but likewise affects the secretion from the buccal glands. This inhibition of the salivary secretion in its aggravated forms is so considerable in certain cases as to result in conditions of actual pain. Enlargement of either the parotid, submaxillary or sublingual glands is exceptional and unusual, but I have been able to find reports of four such cases in literature in which the augmentation was limited in three to the parotid, and in the fourth case, in addition to the parotid involvement, the submaxillary became similarly affected. This increase in size of the parotid gland occurs in two different forms: one, in which the parotid gland remains permanently enlarged, and in the other in which the augmentation in size is intermittent and very variable in duration. The only case of permanent enlargement of the parotid in this disease is that reported by Dr. Thomas Harris[3]; those of temporary duration were recorded by Mr. Jonathan Hutchinson[4] and by Dr. Battle.[5] The case observed by Dr. Battle is the only one in which, in addition to the parotid enlargement, the submaxillary gland has shown implication. This consisted of an intermittent augmentation in size, recurring at intervals of three or four weeks.

Another curious symptomatic association with the mouth dryness in some cases is the accompanying dryness of the mucous membranes of the nose and eyeballs, so that in the latter case the patient is quite unable to shed tears. A case of this kind was published some years ago by professor Fraser of Edinburgh.[6] The sense of taste and smell in a few recorded instances is mentioned as having suffered depreciation, but this is rare and when present variable in its degree. In Dr. Harris' patient this impairment was moderately well marked.

The occurrence of a marked diminution of the cutaneous activity consequent upon the onset of the salivary disturbance in my patient, and the apparent existence of a functional intimacy between the salivary structures and the cutaneous apparatus is indeed curious in view of the fact that these organs are apparently totally unrelated, not only from an anatomic standpoint but likewise physiologically. This association of a cutaneous trouble with xerostomia is unique in the literature of dry mouth. The nature of this disturbance no doubt belongs to that same category as those in which the lacrimal and nasal secretions were interfered with.

As already mentioned, the salivary involvement includes physiologic derangement of more than the parotid glands alone. The other salivary and buccal glands also exhibit the same phenomena observed in the other implicated organ. The arrest of the gland secretions of the mouth cannot be explained on the ground of structural alterations in the parotids which are, apparently, very infrequent in the first place, and, moreover, the acceptance of such a conception would offer no pathologic solution of the functional implication of the other functionally affected structures.

The opportunities for the anatomic study of the organs from this class of cases have been extremely scanty and uncertain, but probably the records of future extended researches will bring evidence which will justify the classification of this disease as one of functional derangement of the nervous system. There is much, in the light of our present knowledge regarding this affection, which points to it as of this nature. The intimate relationship of the cutaneous function with the salivary trouble and the corresponding fluctuations of functional activity of both sets of organs, as well as the clinical evolution of the disease, in the case here reported, strongly suggests the probability of a functional disorder of the nervous mechanism. In same of the cases recorded a definite neurotic history is mentioned, but not in all. In the patient, the subject of this report, the neurotic factor is prominent and lends some additional support to the theory of the functional character of the malady.

Xerostomia is essentially a disease of middle or advanced life, the occurrence of a case in a subject under forty years of age being quite exceptional; the majority of the patients are more than fifty. It is

interesting to note that these patients are, with the exception of the features peculiar to this disease, apparently quite well in every other respect. Sex apparently predisposes to its production since almost all the cases thus far observed have occurred among women. The onset may either be sudden or, as is more often the case, insidious.

As regards treatment little can be said of a very certain nature except, perhaps, that the prognostic results have proved uniformly bad, as far as a complete cure is concerned. Dr. Arthur J. Sharp[7] has very recently published an instance in which much improvement occurred from the use of medium-sized doses of mercuric iodid and quassia. Pilocarpin as a therapeutic agent of temporary benefit has probably yielded the best results in the hands of others, as well as in my own.

THE TREATMENT OF ADHERENT RETROPOSED UTERI.[1]

BY W. R. PRYOR, M.D.,
OF NEW YORK;
PROFESSOR OF GYNECOLOGY IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; CONSULTING GYNECOLOGIST TO THE CITY HOSPITAL.

THERE is much information desired regarding the exact manner in which the adhesions are produced. Certain cases give no history of labor or abortion, no attacks of gonorrhea, no unclean intra-uterine manipulations, yet upon examination, the retroversion and fixity are perfectly apparent. Upon operating for the relief of such a case little or no disease of the ovaries or tubes is found. The question suggests itself: Could not the effusion of lymph be due to the displaced uterus resting immobile upon a portion of bowel equally fixed, the rectum, and be an exponent of a low form of peritonitis due to migration of pathogenic germs from the bowel? It is this form that we see most often in robust servant-girls. The period at which the displacement occurred is unknown, as is the time when the union took place between the uterosacral and rectal structures, and the uterus. These women are very often untouched virgins. The bladder is attached low down on the uterus, and the anterior vaginal wall is remarkably short. Upon severing the adhesions the uterus can be lifted up, but upon being released immediately assumes a retroposition again. Retroflexion is as marked as retroversion. I have been unable to cure such cases by any operation. Fortunately they are rare. I have met with but five. I have classed them as congenital and incurable by any known operation. The vagina is too short for either hysterorrhaphy or the operation through the posterior cul-de-sac. They are either congenital or have originated early in infancy.

As we commonly meet with adherent retropositions, they can generally be traced to some form of infection, Abortion and labor followed by sepsis undoubtedly cause most of them; but gonorrhea is found to produce them also. According to the manner in which the infection reaches the peritoneum, the complicating lesions in tubes and ovaries will vary. The most pronounced adhesions are found in cases recently pregnant, and those cases also present the least amount of tubal disease. Where gonorrhea causes the retroposition and fixity the tubes are most damaged, and the adhesion between the uterus and the retro-uterine structures is least. As a result, we find that conservative treatment of the adnexa in the cases following pregnancy can be most often applied, while in cases of gonorrheic orgin, the adnexa are most frequently to be sacrificed.

Certain it is that at the time of operation, in all cases, the degree of adnexal disease is found to be far more extensive than was revealed by examination. And so it happens that those who have seen many of these cases from the peritoneal side are loath to recommend massage and forcible replacement.

Because of the very usual presence of more or less disease of the tubes and ovaries, operations for the relief of adherent retroposition are not to be judged by the number of pregnancies which follow. Rather is a pregnancy subsequent to the operation to be considered a triumph of such conservative work as has been applied to the adnexa. But should pregnancy follow any operation for adherent retroposition and be interrupted by conditions existing in the maternal organs, which conditions were present before the operation or induced by it, I should say that that operation was a failure.

I would, then, apply these tests to all operations which seek to remedy the conditions under discussion:

1. If the woman has conceived and aborted while the displacement existed, and this has not been followed by an increase in the pelvic lesions, the op-

[1] Read before the American Gynecological Society, Boston, May 24, 25, and 26, 1898.

eration should place her organs in such condition that she can go to full term.

2. If the woman has been sterile before the operation, and remains so afterward, the operation is to be judged by (*a*) the position of the uterus after a fair lapse of time; (*b*) the correction of disagreeable symptoms; (*c*) the improvement in the functions of the parts.

In all operations seeking the correction of these displacements the first step is to free the uterus and place it in the class of movable displacements. This accomplished, treatment of the coexistent tubal and ovarian disease is to be undertaken, and, finally, some means must be adopted to retain the replaced uterus in a position resembling the normal. But it it will not suffice to assemble the organs in a relatively normal relation. All operations upon the displaced uterus must be performed with due regard to its function. Any operation which very generally interrupts a future pregnancy is to be condemned; and an anterior fixation may as surely prevent ascent of the pregnant uterus as will a posterior attachment. If this anterior attachment is low down an interrupted pregnancy is to be expected. This objection does not attach to fixation high up. The operations which proceed between the bladder and uterus, and end by attaching the uterus beneath the bladder, are very generally condemned. They all proceed from above the uterus where the adnexal lesions are approached, and are open to all the objections which attach to operations which provide no escape for the oozing produced by severing adhesions and conservative treatment of the adnexa. The same objection is found to hysterorrhaphy. But the operation through the belly is really attended by less traumatism than that incident to separating the bladder from the uterus, and has the advantage over the latter of facility in execution and freedom from bad influence over a subsequent pregnancy.

But not merely the question of the position of the uterus is involved in the discussion. If it were it is probable that the hysterorrhaphy of Kelly would be the operation of election in all cases. Certainly it is to be so considered where removal of either ovary or tube is rendered necessary because of pus. And in that word, *necessary*, we have the whole gist of the matter. All operations anterior to and above the uterus make no provision for the escape of fluids. As a result, it is found "necessary" to remove certain adnexal lesions which may be conservatively treated; oozing and serous discharge could be drained away. I refer to those more chronic ovarian and tubal lesions which are unaccompanied by the formation of pus. These are ovarian apoplexy, cystic ovaries, occluded tubes, adherent ovaries and tubes, hydrosalpinx, and small broad-ligament cysts. To split open a diseased ovary, peel out the lining to the sac of a blood-clot, puncture cysts, trim the edges and suture, without making provision for the oozing which inevitably results, is to subject the patient to some risk when the operation is done through the belly. The same may be said regarding the treatment of hydrosalpinx and the formation by suture of a new mouth to the tube.

These lesions are undoubtedly brought about by pathogenic germs, and although no pus may be present at the time of operation, yet no one can insure the absence of germ life. It is undoubted that the conservative treatment through the belly of these various forms of tubal and ovarian disease is attended by rise in temperature and mortality. I do not think any forcible objection can be made to hysterorrhaphy, except that the removal of certain ovaries and tubes is found necessary, which removal would be unnecessary were the treatment by another route.

Almost any operation which invades the pelvic cavity can convert a fixed into a movable uterus. In that respect one has no advantage over another. Where incision of capsules containing fluid, the result of inflammation, is done, the escape of possibly infected fluid is necessary. This infection of the fluid is particularly likely in the case of occluded tubes. And in all such evacuating operations, whether performed upon the tube or ovary, the free and untrammeled escape of the discharge is of the utmost importance, not only to the individual as a whole, but also that the structure operated upon may exercise to its fullest its powers of repair. And if this evacuation be made in such a way that the parenchymatous oozing is removed immediately it is produced, as well as the fluid contents of the sac, it is apparent that hemostatic suture will not be necessary. Such a suture is unfortunate in all evacuating operations. It is strangulating to the tissues, thereby limiting repair, locks in discharges, and introduces a foreign material which must be taken care of.

If we can perform these evacuations without suture I believe the repair will be more thorough than when suture is used. To attempt this by any of the anterior operations would be to subject the patient to more danger than to remove the organs. Through the posterior cul-de-sac the pelvis is entered at its lowest point. When the incision is properly made and a certain posture of the patient secured, the operator can see as much as through the abdominal incision. Meeting a hydrosalpinx, an occluded thickened tube, cystic or apoplectic ovary, or small broad-ligament cyst, he is free to incise and trim the tissues as much as may be thought necessary, and to leave them oozing. Suturing is necessary only

when large portions of the ovary are removed, opening small, spouting vessels. Although all operations entering the pelvis are equally effective in severing adhesions, the posterior cul-de-sac operation, because of the position of the incision, enables the operator to apply conservatism in a class of cases and in a manner which he dare not attempt by any other operation.

The last question raised by me relates to the effectiveness of the various procedures in correcting the displacement and maintaining the uterus in a relatively normal position. There can be no doubt that the uterus is held upward and forward by hysterorrhaphy. I am willing to admit that the same is true of the intra-abdominal shortening and suture of the round ligament—the operations of Wylie and Dudley, and the intravaginal operation of Goffe. But I refuse to concede that the indications for treatment in adherent retroposition are met by the operation between the bladder and uterus, after Mackenrodt and Dührssen. These operations place the uterus forward, but also bind it down. Nothing can be said by me against them stronger than the statistics quoted by Edebohls. But having obtained such excellent results from another anterior operation, namely, hysterorrhaphy, the indication for the Mackenrodt or Dührssen or similar procedure scarcely exists apart from the more or less sentimental idea that a vaginal operation is done instead of an abdominal section.

Another operation, or rather, series of operations, is proposed for the relief of adherent, retroposed uteri. I have heard that by some the cul-de-sac is opened and the uterus freed, after which Alexander's operation is done. This unnecessarily elaborate combination would undoubtedly be admissible if Alexander's operation did not produce the frightful disability noticed as a sequel. There have been twenty-four inguinal hernias noted at the New York Hospital for Ruptured and Crippled, in the service of Drs. Bull and Coley. The hernias varied in size from a hen's egg to a cocoanut. With one exception they all occurred within one year, and sixteen within six months after the operation. Many were bilateral; they were produced by nearly every man who performs Alexander's operation in New York. I, myself, have reported twenty odd cases and showed photographs. Of course, there may have been duplicates in the two reports, but we are safe in saying that at least Drs. Bull and Coley have seen twenty-four cases. Can any other operation proposed for the relief of so slight a lesion as unattached retroversion show so many grave sequelæ? Then why introduce the element of hernia in the treatment of adherent cases? I fail to see the necessity for subjecting women with adherent uteri to the danger of inguinal hernia. I am convinced that hysterorrhaphy is the preferable operation of all those which proceed from in front of the uterus.

The Operation through the Posterior Cul-de-sac.—Up to January, 1897, I had operated fifty-one times. Up to May, 1895, I had operated six times. I have no means of knowing the result of this first work at the present time; but all the patients were well after three months and the uterus in good position, with one exception. I have to record one failure at three weeks in a gonorrheic woman who removed the dressings so she could masturbate. Of the next series of twelve cases, two reported pregnant and were confined by my assistant, Dr. Torrens Of the other thirty-three I have heard of one pregnancy.

Briefly described, the operation proceeds as follows: After thorough preparation of the vagina the uterus is curetted. Selecting the fold behind the cervix which marks the reflection of the vagina, I enter the cul-de-sac of Douglas. A careful digital exploration is made. The incision is then spread laterally until I can introduce the posterior retractor. The uterus is lifted up into the abdomen by the curved trowel, and several gauze pads are inserted into the pelvis. I then throw the patient into Trendelenburg's position, and am enabled to see and treat the adnexa as desired. Suffice it to say that I feel secure in incising large hydrosalpinx, cystic ovaries, subperitoneal cysts, blood-sacs in the ovaries, and in doing to these structures just so much suturing as they demand, but I try to avoid suturing for reasons stated. If I find a pus-focus in any structure I do not view the case as one of displacement, but as one of suppuration, a subject not under discussion.

I have not yet thought it necessary to remove any of the various results of tubal and ovarian inflammation, so commonly associated with retroversion, unless pus was present. I have operated while symptoms of gonorrhea were present and occluded tubes existed. I have removed small ovarian cystomata and replaced the adherent uterus. But I exclude all cases showing pus. After completing the operation I wipe the pelvis dry and introduce several folds of iodoform gauze just within the incision. These and the uterus are replaced *en masse*, the cervix being forced as high as the vagina will admit. I then lightly pack gauze around the cervix until that portion of the vagina which is above the levator ani muscle is almost filled. A stout roll of gauze is then made, varying in thickness and length to suit the width of the vagina. This is inserted transversely above the levator-ani fibers. It lies in front of the cervix, its ends resting in the lateral pelvic cavities.

By this the cervix is kept anchored and cannot descend. I sometimes pack the uterus with gauze. A stationary catheter is inserted and the sphincter ani dilated.

By the second day the bowels have moved, the bladder is irrigated, the catheter is withdrawn, and if intra-uterine packing has been used, it is removed. In from seven to ten days, varying with the amount of oozing produced by the operation, I place the patient in Sims' position and remove and renew the dressings under chloroform. The dressings are repeated until the cul-de-sac closes. The patient is out of bed in two and one-half weeks. I maintain the vaginal support for six weeks continuously, always employing the transverse pessary of gauze for this purpose. If amputation of the cervix and perineorrhaphy are indicated, they are performed in three months.

The operation, so far as I can find the results, succeeds perfectly. Several patients have reported pregnant, and two have been confined successfully. I seek by this operation to sever adhesions binding the uterus down. Next, those degrees of ovarian and tubal disease which, when the anterior operations are done, require removal of the organs, I treat conservatively. By replacing the uterus as I do, with the gauze behind the cervix, I seek obliteration of the cul-de-sac and the formation of a mass of plastic lymph between cervix, uterosacral ligaments, and rectum. As a result, the scar-tissue formed after healing is completed holds the cervix fixed upward. As the cervix cannot descend, the corpus uteri is thrown forward by the intra-abdominal pressure.

All those replacement operations which succeed obey one or two rules—either the corpus uteri is fastened high and forward, or else the cervix after replacement is fastened high and backward. The first fixes the body of the uterus, while my operation leaves it free.

The fear has been expressed that possibly hernia may occur through the scar. This is impossible, because the scar is thicker than the normal vagina, and is under the protection of the sacral promontory. That the operation succeeds is due to the formation of lymph effusion between the cervix, rectum, and uterosacral ligaments. The cervix being held high, and the corpus free, there is no tendency to abortion. The uterus is limited in its area of mobility in one direction only—downward movement of the cervix.

The after-treatment is undoubtedly troublesome, as is the treatment of all open wounds. It is also technical, and must be precisely carried out. To allow the cervix to descend and retroversion to occur before the post-cervical lymph has been converted into fibrous bands is to invite an ill result.

In December, 1896, I performed this operation upon a patient. One year afterward I opened the abdomen for appendicitis. I found the corpus uteri perfectly free. The direction of the bands suspending the cervix was as follows: One band, very broad, ran from deep in the cul-de-sac to a point two inches up on the rectum, measuring from the bottom of the cul-de-sac. Radiating from each side of the cul-de-sac were a number of slender bands extending to the uterosacral ligaments. The cul-de-sac was not obliterated, neither had the lymph been converted into a broad sheet. The ovaries and tubes were perfectly free.

Twice after doing this operation I have opened the belly at the same sitting; in one case, to inspect the appendix and to prove wrong the diagnosis of appendicitis, made by several surgeons; and again, to recover a lost gauze pad, the string of which had broken. In neither case could I see the gauze in the cul-de-sac, and the ovaries and tubes were entirely away from the gauze. Should the gauze be pushed high up behind the uterus the lymph forming around it would implicate the ovaries and tubes.

I elect one of two operations in all cases in which I operate for adherent retroposition. If there be occasion to remove the adnexa or a large tumor, I perform laparotomy and hysterorrhaphy. In all other cases I operate through the posterior vaginal fornix as I have described.

CLINICAL MEMORANDUM.

COLLOID DISEASE OF THE OMENTUM. GANGRENE OF THE LEG; AMPUTATION; RECOVERY.[1]

By. F. J. BOWEN, M.D.,
of Mt. Morris, N. Y.

Case I.—A man about sixty-seven years of age presented himself to me with what appeared to be a hydrocele. The sac, however, was not translucent. I tapped, and drew off a dark, watery, "cancerous" looking fluid. Within a short time the scrotum was again distended, and a few days afterward the fluid could be seen distending the inguinal canals and reaching the abdominal cavity. In the course of a few weeks the abdomen became so distended that tapping was decided upon. A large-sized trocar was employed, but the accumulation would not flow; it was found to be thick and jelly-like, of a white, transparent color.

I suggested that some one else see the case. My medical friend very promptly made a diagnosis of ascites, and repeated the operation with the same result. The operation was repeated once afterward by a doctor sent to the

[1] Read before the Livingston County, N. Y., Medical Society.

patient by relatives without previously acquainting the patient with what he proposed doing.

The abdomen gradually became enormously distended, and the whole lower part of the body became infiltrated with this peculiar substance which oozed from the skin. Death occurred in the course of six or eight months from exhaustion. A post-mortem revealed two or three pailfuls of this peculiar material in the abdominal cavity. The intestines were pigmented. The omentum was a shriveled, thickened mass about the size and thickness of one's hand, and the fingers crumpled through it very readily. It reminded me of a slice of turnip, punched full of holes, thus forming the stroma, which yielded this colloid material. The diagnosis, of course, was colloid disease of the omentum.

CASE II.—The second case I report to show that a physician should never abandon what appears to be a hopeless case as long as there is a thing left for him to do; and also that it may assist one to decide as to the advisability of operation in a similar case.

A farmer, nearly sixty years of age, with no history of rheumatism, but of more or less hard work, began to have symptoms of heart failure. In the course of a year, when I was called again, I found his feet and ankles edematous. A very faint aortic regurgitant murmur could now be heard for the first time. A few days later it could be seen that the left ventricle was undergoing what I should consider rapid dilatation, the apex beat changing location perceptibly. He was put on tincture of digitalis and nux vomica, with nitroglycerin to be taken at the time of the sinking spells. The edema advanced in spite of treatment. At this time, feeling that something extraordinary should be done, he was given the "Da Costa" tablet, with the result that he was let down more rapidly than ever. He became partially comatose, so that for a week he hardly realized his condition or recognized members of his family.

Compression from the edema stopped the circulation in the feet. Punctures were made through the skin. He was again placed on digitalis and nux vomica, which, with compound jalap powder, gradually reduced the edema, the heart becoming stronger. Circulation returned to his right foot, but the left was damaged beyond repair. The gangrene extended to within about two inches of the knee. His general condition improved. His heart became able to run itself, which enabled him to take iron and a bottle of cod-liver oil. The gangrenous limb was kept packed in carbolized charcoal, awaiting the time when we could bury all of him together. Hot weather came on. The odor began to annoy the family, and one day he sent for me and asked my opinion of amputation. He was told frankly that he understood the condition of his heart. It was doubtful if he could survive an operation, but that he certainly could not live long without it. He replied that I could get ready and do it.

He was again placed on digitalis and nux vomica, and amputation above the knee decided upon for the third day after. Dr. Kneeland of Dalton was asked to attend to the most responsible part of the operation, the anesthetic. Ether was given. The heart showed the strengthening effects of the medicine, and pounded its way through without a skip. Dr. Brown of Nunda assisted at the operation. As near as practicable it was done aseptically. The silk was boiled, and every vessel was tied with it. No iodoform was used with the first dressing. The gauze had been sublimated, but afterward boiled, so that it was simply sterile. Following the operation he was given whisky, milk, and protonuclein. The wound healed very promptly, and the man is alive to-day, thirty months after the operation.

MEDICAL PROGRESS.

The Sudden Death of Young Infants.—BERTHOLD (*Centralbl. für Gynäkol.*, August 6, 1898) calls attention to the rapidity with which young infants sometimes die, although no cause is apparent. Sometimes at autopsy an enlarged thymus gland has been found, so that the writer believes such a gland to be the cause of death. According to his idea hypertrophy of the thymus may, unaided, cause death in young infants. In suitable cases, therefore, when the life of a child is threatened, a hypertrophic thymus may be removed in whole or in part.

Excesses in the Treatment of Infants. — NEUMANN (*Centralbl. für Gynäkol.*, August 6, 1898) refers to some of the injuries which may be inflicted upon very young infants by too much zeal in the care of them. In the first place, the bath may infect an otherwise sterile navel string. A rapid and complete mumification is the best protection against this accident, and the rule should, therefore, be to keep the navel dry after the child has been given its first bath. Another danger which often accompanies a bath is the too great cooling of the child's body. The careful cleansing of the mouth of the new-born child is unnecessary and often harmful, since it may result in infiltration of the mucous membrane, or even in ulceration. The snipping of the frenum of the child and the lancing of the gums are useless procedures, which are not entirely given up as yet. In case a healthy child is born the physician should be most careful not to depart from hygienic and dietetic rules. If a disease develops he should be ready to meet it in its beginning, hence the necessity of constant supervision of a new-born child.

The Position of the Transverse Colon.—COHAN (*Gaz. Heb. de Med. et de Chir.*, June 5, 1898) ridicules the idea that there is a single position for the transverse colon, which he says is the most movable part of the large intestine and may be found in any portion of the abdominal cavity. If the colon and its mesocolon are short, its position is usually transverse and rectolinear. If they are long it occupies a lower position in the abdomen, often reaching into the pelvis. In other conditions it may be drawn upward so as to occupy an unusually high position. Its right extremity is always situated lower than the left. Its great mobility causes it to lie in front of most of the abdominal organs. It may thus be a source of error in clinical examination of the abdomen.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, OCTOBER 29, 1898.

THE PLAGUE IN VIENNA, AND THE REGULATION OF BACTERIOLOGIC INVESTIGATION OF EPIDEMIC DISEASE.

THE announcement of the death in the General Hospital at Vienna of one of the attendants in the bacteriologic laboratory of Professor Nothnagel's clinic supposedly from bubonic plague, looked at first as though it might be a newspaper canard, for now that Spanish war alarms are o'er, some of the papers find themselves sadly put to it to find the necessary matter, of a kind sufficiently sensational, to tickle the cloyed appetites of readers accustomed to be regaled at breakfast with a battle or two and a sea fight; and so not everything that finds its way to the composing-room is gospel truth. There comes, however, as we go to press, the confirmation of the first dread rumor and its sad substantiation by the report of the death, from the same disease, of Dr. Müller, Professor Nothnagel's assistant.

It is not at all likely that the disease will spread beyond those who have been in immediate contact with the infecting material. That there is very little cause for alarm may be judged from the fact that of all those (some twenty in number) sent by the various governments of Europe to investigate the disease in India where it was raging severely at the time, but one, so far as we know, contracted the disease. He was a member of the German commission, who cut himself while performing an autopsy, and whose attack was very mild and ended in recovery. There is naturally not a little excitement among the people of Vienna, though Virchow and other distinguished medical men have sent their positive assurance that the disease, though infective, is *not* contagious, and there is no liability to an epidemic. In a few days the episode will have ceased to occupy public attention.

Another medical martyr is added to the list of those who have in recent years laid down their lives in the study of disease. The list is not a short one now. Not the least distinguished name on it will be that of the brilliant young medical man, some of whose work had already attracted attention, before the report of the Austrian plague commission brought him prominently before the medical world. The lesson of his death is an important one and should not be overlooked. It is that in handling virulent cultures of bacteria as in everything else, however fraught with danger it may be, familiarity breeds a contempt of danger that finally results in neglect of the proper precautions.

The purpose of study is a most commendable one; it deserves encouragement in every possible way. The detailed study of this very bacillus of the plague, attended as it has been always by the most serious danger, the danger being faced by hundreds of observers without a thought that they were heroes, has given the world a knowledge of the exact nature of the cause of the awful black plague so much dreaded heretofore, that will easily enable the profession to guard Europe from its ravages for all time. While we have insisted on the improbability of any epidemic of the disease attacking the city, there is no doubt that it is extremely imprudent, to say the least, to import the germs of foreign epidemic disease into the heart of crowded centers of population.

There is no necessity that such studies should be undertaken in large cities. So far no epidemic of disease has ever been started by carelessness in the handling of bacterial cultures. As the bacteria specifically causative of zymotic diseases become better known, however, and more and more

varieties of virulent cultures are kept for purposes of study, it is evident that the dangers of such an outbreak of disease from neglect of proper precautions will be always on the increase. One epidemic thus started might be enough by the popular feeling it would justly create, to hamper bacteriologic study for years.

It would seem, therefore, that now is the proper time to take precautions against such a deplorable possibility. An ounce of prevention is worth a pound of cure. A law, for instance, forbidding the bringing of cultures of any disease, not endemic to a city, into that city except under most stringent precautions would seem to be the remedy, for scientific enthusiasm will sometimes make even the most level-headed rash. A law making all experimental work with such cultures illegal, except in properly guarded laboratories and not situated in cities, would seem to be no more than the circumstances demand.

Of course there is the danger and there will surely be the protest on the part of bacteriologists that such regulations would hinder the progress of science. Perhaps, to some slight degree, it would at the present time, because research laboratories are unfortunately situated only in large cities; but a proper care for the public health seems to demand such regulation. We might have learned more of certain of the contagious diseases, smallpox for instance, if in recent times we had not quarantined so thoroughly the cases that occurred, but no medical man objects for this reason to the quarantine. Certainly even now anything like experimental study of the supposed bacillus of yellow fever conducted in the summer time especially in any of our large cities would be against the better judgment of the medical profession generally in such matters.

There is involved in this matter a grave weight of responsibility on the part of the medical profession toward the public health. Nothing of a serious nature has yet occurred, but it behooves us to preclude the possibility of anything occurring. The fair name of modern scientific medicine is too precious to permit of its being smirched by the blot of an epidemic of disease introduced into a closely packed population because of defective precautions during the study or demonstration of its bacterial cause. The matter is, in its way at least, as important as the manufacture of high-grade explosives. No amount of care or knowledge of the personal danger involved will ever quite protect men from becoming habituated to the risk involved and being tempted to some indiscretion whose consequences may be far-reaching. Measures should therefore be taken at once, the initiative coming from the medical profession itself, for the legal regulation of such study, lest some sad mistake should precipitate an outburst of popular feeling that would seriously hamper the progress of scientific medicine.

CHRISTIAN SCIENCE AND NIHILISTIC THERAPEUTICS.

THE cable last week brought us the sad news of the death of a well-known American literary man in England at the untimely age of forty-two. It brought us also the news that he had been tended in his last illness, at his own request, by a Christian scientist, and that an investigation into the cause of his death had to be legally made before a burial permit was issued. Harold Frederic was not the first, by any means, among the intelligent class of the community who took up with the latest fad, Christian science. His state of mind is by no means a rare one even among people of his class. It would seem worth the while then to stop a moment and ask ourselves why it is so; and then the natural and very practical question, Is there anything in the attitude of the modern physician toward his art that is an occasion for it? It is very easy to say that the sect or school (which shall we call it?) is neither Christian nor scientific; that no Christian sect would admit any kinship with them, and no scientist allow for a moment any claim of theirs to be permitted to hang, however precariously, on the skirts of science. To sum the whole thing up as an imposture, brought into prominence because it is the fad of the moment, and then put the matter aside as if that were all about it, is one way of disposing of the question but not a very satisfactory way.

The fact is that this is an age of unrest and of unsettled opinions. The old faiths are losing their hold on many minds and among the others the faith in the physician. There is a reason for this want of medical faith just now more than before, because practical medicine is in a transition stage. At least it comes to the lay mind that this transition is taking place just now, though it has been insensibly

in progress for a good while. The abandonment by medical men of the old doctrine of specifics for disease is just being realized by the non-medical. In the midst of the mental state of hesitation in medical matters induced by the realization of this change of base, the time spirit of heresy, for the Greek root αἵρεσις means free choice, has gathered worshipers before some odd medical shrines. This is essentially the age of quacks and charlatans, of faith cure and mind cure, of water cure and air cure, of drug cure and diet cure, while the regular practitioner no longer claims to cure at all, but only to help Nature in her effort to restore the equilibrium of organic economy.

Meantime physicians themselves have been not a little to blame for the present condition of therapeutic incredulity in the popular mind. With the gain in our knowledge of pathology that followed the great work of Rokitansky and the Vienna school, there came a wave of nihilistic therapeutics over scientific medicine. To the pathologist, who could point out on the autopsy-table the absolutely irreparable destruction of tissue in kidney and liver and intestine and heart and lungs, it seemed absurd to give medicines for organic disease, and so it was and is, if there is included in its exhibition any hope of curing the organism by the repair of organic changes. But there is another side to the question.

Humboldt when comparatively young is said to have remarked that he would not care to be responsible for the invention of an optical instrument so faulty as is the human eye. Later on in life, he expressed his admiration for it in no measured terms, as an optical instrument that had within itself wonderful powers of compensation. The human body is such an instrument. It has within itself almost untold powers of compensating for even organic changes that have taken place.

Symptomatic treatment, though the term has been the subject of no little derisive aspersion, is the fulfilment of the mission of therapeutics to aid Nature in her compensatory effort, for symptoms are but the signs of failing compensation, the guides as to when and where and how we may be of assistance to Nature in her struggle with disease. Treatment is no longer the direct battle that it was for so long thought to be with the *ens morbi* itself, but it has thereby lost nothing of its dignity as the practical expression of what medicine can do for the patient. The young man straight from his books and his autopsies and his microscope and his bacteria may think little of symptomatic treatment because it smacks of empiricism and has none of the direct demonstrative effect that strict science demands, but the old clinician after long years in the actual study of cases, after long experience in the treatment of disease, and withal a knowledge of pathology that may be thoroughly up to date, *knows* how much good his remedies have done and honors them accordingly.

There has been too much expression given, and by those least justified in giving it, to a lack of faith in remedial measures. Under the influence of the feeling of disrespect for what is called mere symptomatic treatment, by certain misguided, mostly young medical men, the good that may be done for symptoms is, as one of our distinguished old clinicians has recently said, left undone until symptoms have gotten beyond control; while if they had been conscientiously recognized and treated from the beginning much good might have been accomplished. The practice of medicine is an art, not a science, and is likely to continue so for many years yet to come. It is bound to have in it those elements of the personal that make the practise of any art unsatisfactory to its devotees, because they fail so notably to reach their ideals, and recognize that fact. This spirit of dissatisfaction is in itself, however, a blessed privilege, for it is the surest earnest of renewed and continued effort, the best mark that the art is ascendant, not on the wane.

It is a matter of serious importance, however, that this spirit of dissatisfaction at a period of transition in medical beliefs, such as exists at present, should not be communicated to those who are unable to realize its significance, nor gage its promise for future progress, but who simply translate it into terms of failure of the ordinary therapeutic methods so long accredited. As said, the members of the profession most liable to convey such impressions, while calculated by their scientific attainments to win credence and acceptance for statements of theirs, are, as a rule, just the ones whose relations to the practical treatment of disease have least fitted them for the expression of therapeutic or atherapeutic opinions. It is much easier to be a nihilist in therapeutics, as in most other things, than to be the inventor of use-

ful curative procedures. But the world will honor not the men, who gave up because the system was imperfect and wished to wait inactively for the future to reveal better methods, but those who manfully set their hands to the work, and though with imperfect tools, accomplished to the best of their ability the work their hands found to do—struggling through darkness to the light—*per aspera ad astra*.

TYPHOID FEVER IN THE FRENCH ARMY.

We have learned that typhoid stools when mixed with drinking-water will multiply the number of cases of typhoid fever in a camp. This simple lesson had already been learned by many communities in civil life, recently at Maidstone for instance, but it was reserved for Camp Thomas to teach it to the army officers. There was served daily at this camp the diet which the Assyrian monarch prescribed, and the results show what a meaning curse it was that his cup-bearer, Rab-shakeh, hurled into the face of the King of Israel. They learned the same lesson in the French army a good many years ago. Perhaps it may be interesting to see how they profited by their experience.

In 1895 the Eleventh Army Corps of the French army numbered about 11,000 men, of whom some 600 had typhoid fever every year. Something less than 100 of these patients died. Since 1886 the mortality has never reached 30; while in 1896 there were only 8 deaths, and in 1897 only 7 from this cause in this large body of men. The officers have been learning their lesson, and as a result, the number of cases of typhoid fever which developed annually in this portion of the army has been divided by 24, and the mortality from typhoid by 25.

It was not by reason of natural surroundings that the present favorable figures have been obtained. The Eleventh Corps is stationed in one of the worst districts of France, a region of which it has been said, "Tuberculosis kills the inhabitants, and typhoid fever keeps the doctors alive." Most of the villages are in an unsanitary condition. Leaky privy-vaults and open ditches containing fecal matter contaminate the subsoil, while in the absence of running water, well water is used for drinking and cooking. The municipal councils are for the most part innocent of any knowledge of hygienic laws, and public disinfection, isolated treatment of infectious disease, or even official notification of the same are usually neglected. Nevertheless in such unfavorable surroundings the sanitary corps of the army has been able little by little to introduce measures which have raised the standard of health in that district, until its soldiers show the very best record of the whole army. These sanitary measures are briefly: Continuous ventilation of the sleeping apartments; frequent whitewashing of the walls; rendering the floors impervious by coal-tar; removal of dust in a moist condition; introduction of hand-basins and shower-baths; increased rations in the field, and a greater variety of food; substitution of tight movable water-closets for the old privies and ditches.

In spite of these changes, typhoid fever continued its ravages, especially in certain garrisons, although in lessened degree. Well water was still in almost universal use.

In 1889 most of the wells were condemned and, wherever possible, spring water was conveyed to the garrisons. Where this was not practicable Pasteur-Chamberland filters were provided. As a result of these measures the number of cases of typhoid fever fell below 10 per cent. per year for the first time in the history of this army corps, while the deaths fell below 20. As long as the region in which it is situated is so completely infected with typhoid as it still is, it will be impossible to stamp the disease out of the army entirely; for no matter how carefully the water-supply of the garrison is guarded, one cannot prevent a soldier from drinking outside of the barracks.

If typhoid fever breaks out or is suspected, the clothing and bed-clothing of the sick soldier are sterilized by steam under pressure at 115° C. (239° F.), and the walls and floor of his apartment are disinfected by powders or by solutions.

Is there anything for America to learn from this account of France's experience as given in the *Gazette Medicale de Nantes*? Could any words be more suitable to the occasion than those with which the writer closes? "Nowhere is there a plainer triumph of prophylaxis, based upon a knowledge of the general causes of disease, than in our land army, . . . thanks to the ingenuity, vigilance, and energy of the *eminent technical chiefs*, to whom the sanitary direction of affairs has been so happily confided. It is also necessary to recognize that success is in part

due to the solicitude and authority of the commander, who has exacted obedience to these preventive measures." "*Eminent technical chiefs!*" And commanders who command!

ECHOES AND NEWS.

Mules in Cuba.—The mules sent from the United States to Cuba seem to thrive well there, as only twenty-two have died out of the 1200 sent.

The Wyoming State Medical Society.—The second regular meeting of this youthful organization will be held at the Wyoming General Hospital, Rock Springs, Wyoming, Tuesday, November 1, 1898. A unique number on the program is the report of a case of "foxtail infection."

An Antivivisectionist and Professor Virchow.—During the course of the complimentary dinner tendered Professor Virchow upon his recent visit to London an anonymous telegram was handed to the guest of the evening containing the following words: "Get thee hence, vile vivisector! England spurns thee!"

Poisoned by Toadstools.—Three deaths occurred recently in Trenton, N. J., from eating toadstools supposed to be mushrooms. Five other members of the same family are seriously ill from the same cause, but are expected to recover. The distinction between mushrooms and toadstools often quoted in the country districts is apropos: "Eat them; if they kill you, you will know they are toadstools; if you live, they are mushrooms."

A Spanish Military Academy of Health.—It appears that Spain has at last learned something from her Cuban experience. For the better education of surgeons about to enter the Spanish army a Military Academy of Health has been established at Madrid. Especial attention will be paid to the study of the pathology of tropical climates, the organization of the Spanish and foreign armies in matters of health, regulations, and services, sanitary material, and ambulance tactics.

Death from Stramonium.—The seeds of the *datura stramonium* recently claimed their annual victim in Newark, N. J., in the person of a five-year-old child. It is said that there has been in that city at least one death from this cause every year for the past twenty-five years. The practice prevailing in many of our large cities, as well as in the smaller ones, of allowing vacant lots to produce year after year crops of noxious and poisonous weeds cannot be too strongly condemned. It was by seeds procured from such sources that the recorded fatality was effected.

Longevity in Europe.—From statistics compiled from the mortality bills of the principal European countries from 1881 to 1890 inclusive, the average life in Norway and Sweden is found to be 50 years; England, 45 years and 3 months; Belgium, 44 years and 11 months; Switzerland, 44 years and 4 months; France, 43 years and 6 months; Austria, 39 years and 8 months; Prussia and Italy, 39 years; Bavaria, 36 years, and Spain 32 years and 4 months. From this it would appear that longevity varies directly as the latitude and inversely as the mean temperature.

Army Contract Surgeons to Be Examined.—An order has been issued by the War Department directing the Surgeon-General to convene a board of medical officers to examine acting assistant-surgeons now in the service and candidates for appointment. Up to the present time appointments have been made by the Surgeon-General on professional and such other indorsements as the candidates have been able to present. This course was necessary because of the urgent necessities of the service, and the fact that medical officers were not available for duty on the examining boards.

Injured While Experimenting with Liquefied Air.—While experimenting with liquefied air at the Brooklyn Polytechnic Institute last week, Professor Irving W. Fay of the Chemistry Department was seriously injured about the face, and will probably lose the sight of one eye. He had mixed with it some red phosphorus, and poured out the mass upon a piece of paper on the table, and was watching the changes take place in the phosphorus. He then took up a glass rod and separated the particles, when the explosion occurred which produced the injury. Fortunately, the force of the explosion was exerted downward, wrecking the table.

Contagion in a Public School.—There has been an epidemic of diphtheria recently among the public-school children of Scranton, Pa. The parents of one child who contracted the disease have brought suit for damages to the amount of $25,000 against the school authorities and the contractor who was renovating the plumbing of the school, alleging that the disease was due to sewer-gas poisoning. The plaintiffs will undoubtedly encounter no little difficulty in establishing their claim that the disease was due to sewer-gas poisoning. Indeed, some of the best authorities assert that diphtheria cannot be contracted in that way.

The Troops in Cuba.—Brigadier-General Lawton, who arrived last week on the transport "Michigan," is credited with the following statement: "The American troops, both regulars and volunteers, are very discontented in Cuba, and want to return home. In my mind, the time will never come when the American soldier will serve in Cuba contentedly." He does not like the country and he does not care much for the people. About twenty per cent. of the troops are sick, but this is not due to their not being acclimated, for the same percentage of sickness prevails among the inhabitants. The immunes have not escaped, as was expected, for many of them are sick.

Physicians Honored.—Sir William MacCormac, Bart., and Sir Francis Laking have been appointed Knights Commander of the Royal Victorian Order. Mr. A. D. Frip and Fleet-Surgeon A. G. Dalmego have been appointed members of the fourth class of this order.

These physicians were medical advisers to the Prince of Wales in his recent illness. The Royal Victorian order is bestowed upon "such persons, being subjects of the British Crown, as may have rendered extraordinary, important, or personal service to Her Majesty, her heirs, and successors, and who have merited Her Majesty's royal favor." Only two other physicians are members of this order.

Yellow Fever in the United States.—The recent epidemic of yellow fever was confined almost exclusively to the two States, Louisiana and Mississippi. The total number of cases recorded by the Marine Hospital Service up to October 22nd was 2571 with 141 deaths, a mortality of 5½ per cent. The recent cold weather, which has fortunately prevailed in the Southern Mississippi Valley, has stayed the epidemic, allayed the fears of the panic-stricken inhabitants and raised the exacting quarantine. From this time on it is to be expected that State officials may be found at their posts of duty and the importunate taxpayer may find the proper officer to receive his obligations of citizenship.

Sickness at Manila.—The report of October 23d showed 1801 cases of sickness from all causes among the troops stationed at Manila. Many of the cases are only temporary, and but comparatively few cases of serious illness are reported. There have been a few cases of smallpox. Three deaths from typhoid occurred during last week, and eleven deaths from other causes. One of the most serious difficulties with which the surgeons have to contend is the drunkenness among the soldiers. Manila is full of saloons, and more are preparing to open, so that the outlook in this direction is anything but favorable. Medical supplies have been purchased at Yokohama, and work on the new hospital is proceeding rapidly.

The Annual Meeting of the New York County Medical Society.—The annual meeting of this Society was held at the Academy of Medicine, Monday evening, October 24th. The principal business of the meeting was the election of officers for the ensuing year. The members were divided into two factions, one composed of those who had been active in securing legislation looking to the reform of dispensary abuses, and their friends, and the other faction composed of those conservative members who are disposed to let dispensary and hospital matters regulate themselves. The result was a complete triumph for the latter element. The following officers were elected: President, S. O. Van der Poel; first vice-president, Henry C. Coe; second vice-president, J. Clifton Edgar; secretary, Wm. E. Bullard; treasurer, John S. Warren, the latter being the only candidate elected on the opposition ticket.

Workings of the New Vaccination Act in England.—As a sample of the "conscientious objection" to vaccination the following case is cited: At the Cardiff police court, on September 24th, a young man was granted an exemption certificate on the ground of conscientious objection to the vaccination of his child. One of the magistrates, a physician, took the opportunity to remark that they as magistrates had "conscientious objections" to granting such certificates. He added that the magistrates had a conscientious belief that the law permitted an act of gross injustice to the child, and they regarded the conscience clause as a great farce which would one day end in a tragedy. At another place exemption certificates were issued by two courts to 660 persons for about 1670 children in two hours and a half, at the fee of two shillings a case. The objectors were brought into the court in batches of ten to twenty, and asked whether they had any conscientious objections. Some replied verbally, but many considered a nod of the head as sufficient evidence of their scruples.

Dr. Koch's Recent Visit to Rome.—After a stay at Rome of more than a month, engaged in malarial reseaches, Dr. Koch has returned to Berlin. He was accompanied by his associates, Drs. Pfeiffer and Kossel. One of the objects he had in view in visiting Rome was to ascertain how far the Italian malaria coincides with the tropical form of the same malady, and he has satisfied himself that in all essentials they are identical. He has also been able to indicate properties hitherto unnoticed in the pathogenic germ of malaria as found external to man—properties possessing a distinct prophylactic value toward limiting the diffusion of the malady if not in arresting it at its point of origin. He has, however, to supplement this part of his researches by others on the same lines, and with this object he intends to return to Italy in the spring of 1899. So far he has found nothing to add on the clinical side of the subject; and the Roman school do not disguise their satisfaction at this frank testimony to the practical worth of their painstaking contributions to treatment. They, in turn, are profuse in their acknowledgments of Professor Koch's scientific elucidation of points hitherto left obscure, and are grateful for the impulse he has given to the investigation of problems the solution of which seems now "within measurable distance.

The Plague in India.—According to the latest reports there is a slight increase in both the total mortality and death-rate from the plague. During the two years which have elapsed since its appearance the plague has claimed more than 100,000 victims, and as yet no satisfactory method of treatment has been devised. The inoculation experiments have not met with the success anticipated, and owing to native prejudice cannot be fully carried out. It is claimed that the use of antitoxic serum has been successful in 47 per cent. of the cases treated, but this is a very small percentage for, as in smallpox, a certain number recover with little or no treatment. Of those treated in hospitals, 50 per cent. die within forty-eight hours, and of those who live over three days 50 per cent. recover. From observations carried on since the outbreak two years ago, and from the history of previous epidemics, its spread is found to be slow and the area of invasion small, it being still confined almost entirely to the Bombay Presidency. Owing to the hardships entailed by the former quarantine regulations and to the fact that the plague is likely to persist for several years, these regulations have been modified. A strict medical examination

with disinfection has been established at suitable centers, and the old system of passes abolished. Persons coming from infected regions are kept under surveillance for ten days. But these regulations it is hoped will confine the disease within its present bounds by limiting travel to healthy persons.—*Lancet.*

CORRESPONDENCE.

PROFESSOR VIRCHOW'S LECTURE.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Concerning the address of Virchow which you editorially review in your issue of October 22nd, will you kindly inform the readers of the NEWS in what journals the address has been published?

Truly yours,

GEO. M. GOULD, M.D.

PHILADELPHIA, October 22, 1898.

[We are glad of this opportunity to inform the readers of the MEDICAL NEWS that the editorial review referred to was based upon the original, authentic address as published in the *British Medical Journal.* We are also pleased to call attention to the commendable journalistic enterprise of our esteemed contemporary, the *Philadelphia Medical Journal,* which published the lecture in full, simultaneously with the *British Medical Journal.* The lecture has also appeared in the *New York Sun.*—ED.]

THE FEVER AT HATTIESBURG, MISS.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—The fever we have at Hattiesburg has been declared to be yellow fever, but why I cannot see. It may be it was so declared because of its apparent strangeness, but, nevertheless, I do not believe it to be real yellow fever. Neither do I accept "yellowoid," the new name given by Dr. Souchon of New Orleans to the fever, as a suitable one for the fever here. Yellowoid is an indefinite word and, therefore, we do not know definitely what Dr. Souchon means when he says a disease is "yellowoid." Yellowoid literally means yellow-like, and therefore we might say it is like gold, yellow corn, or anything else that is yellow. If yellow fever was called "yellow" simply, then we might conclude that the doctor means like yellow fever when he says it is yellowoid, but unfortunately for him, yellow fever is called yellow fever.

It is true that jaundice is called "yellows," and, therefore, with some propriety, he might call any disease that resembles, or is like yellows, yellowoid, but unfortunately for him again all who have the fever do not turn yellow, and then again, a person may have the "yellows" without having any fever at all. So "yellowoid" is not the name for our fever.

There is another peculiarity about this fever; it is not contagious, but persons in the same locality where others have it are liable to it too if they are not careful about their health, whether they come in contact with the sufferer or not. This satisfies me that it is atmospheric; that is, it is taken from the air; there are conditions in the air that produce it in one who is not careful in preserving his health. So the yearly alarm we are having is due principally to unskilled boards of health and experts.

ISAAC L. PEEBLES, M.D.

HATTIESBURG, MISS., October 18, 1898.

MEDICAL MATTERS IN CINCINNATI.

[From a Special Correspondent.]

CINCINNATI, October 22, 1898.

AT the regular meeting of the Academy of Medicine, on October 10th, Dr. H. J. Whitacre presented a paper, entitled "A Pathological Basis for the Treatment of Bright's Disease," which was illustrated by the projection-microscope and lantern slides. Delafield's classification of kidney diseases was explained, and each lesion profusely illustrated by photomicrographs and sections. About fifty illustrations were used, and among them pictures of Richard Bright and Malpighius, taken from rare old steel engravings. The paper was discussed by Drs. Rowe, Bettman, and Kiely. Dr. Bettman defended the old classification into an acute and chronic parenchymatous nephritis and an interstitial nephritis; Dr. Rowe made some interesting remarks on the histology of the kidney, and Dr. Kiely spoke briefly on Bright's disease as a constitutional affection in which a lesion of the kidney might be present or absent.

At the meeting of October 17th, Dr. Robert Sattler presented a paper, entitled "Recent Advances in Ophthalmology of Interest to the General Practitioner." The operative treatment of myopia and the use of a two-per-cent. solution of nitrate of silver in ophthalmia neonatorum were the points of main interest. Dr. Christian discussed the paper at length, and aptly referred to the myopic individual as one of the worst types of a cripple. That part of the paper refering to ophthalmia neonatorum was further discussed by Drs. Caldwell, Schwab, Brown, and Thompson.

The Cincinnati Research Society held its first meeting of the year on Thursday, October 13th, in the laboratory of the Cincinnati College of Medicine and Surgery. Dr. Greiwe presented a series of sections showing syphilitic disease of the spinal cord. The sections were taken from a single case in which were present the lesions of a syphilitic meningitis, gummata of the cord and meninges, and softening of the cord in both the grey area and around the central canal. The sections were stained by the Weigert and Pal methods. This organization of a limited number of the scientific workers of Cincinnati did excellent work during the last season, and renewed interest is demonstrated by its members.

Dr. James T. Whittaker selected as the subject of a college lecture last week a very unusual epidemic of smallpox, occurring near Lima, Ohio, to which he had been called in consultation. The epidemic was unusual in the fact that the diagnosis was difficult, and most of the cases had been called chicken-pox and measles by a majority of the local practitioners. None of these patients had been vaccinated, and the epidemic illustrated the necessity of wholesale vaccination in the presence of a

mere suspicion of smallpox. Such precaution had not been taken in this community.

The Board of Managers of the Presbyterian Hospital has issued invitations to the opening of the new McDonald Hospital Building on November 1st.

The Miami Valley Medical Society will hold its forty-second semi-annual meeting at Loveland, Ohio, on Tuesday, November 1st. The Cincinnati physicians appearing on the program are Drs. J. C. Oliver, T. V. Fitzpatrick, C. A. L. Reed, Philip Zenner, F. W. Langdon, and C. M. Paul.

The enrolment at the Ohio and at the Miami Medical College is about the same as last year. That of the former is 205, and of the latter 98.

The vital-statistics report of the Board of Health for September shows the total number of deaths to be 412. Among the infectious and contagious diseases reported were: Measles, 6; diphtheria, 33; scarlet fever, 12; typhoid fever, 37; phthisis pulmonalis, 38; variola, 2.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

NOMINATION OF OFFICERS AND PLANS FOR THE SEMICENTENNIAL ANNIVERSARY CELEBRATION OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY—ELECTION OF OFFICERS OF THE PATHOLOGICAL SOCIETY—HOSPITAL NOTES—THE ELWYN INSTITUTION—OBITUARY—PERSONAL NOTES—A NOTED VISITOR—BOARD OF HEALTH NOTES AND HEALTH STATISTICS.

PHILADELPHIA, October 26, 1898.

AT a meeting of the Philadelphia County Medical Society held October 19th, the following officers were nominated and having no opposition will doubtless be elected at the next meeting: President, Dr. S. Solis-Cohen; first vice-president, Dr. John H. Musser; second vice-president, Dr. Shoemaker; secretary, Dr. John Lindsay; assistant secretary, Dr. Kirby; treasurer, Dr. Collier L. Bower; censor, Dr. Ash. Drs. Kirby, Bower, and Lindsay are nominated to succeed themselves.

The report of the Committee of Arrangements for the celebration of the semicentennial anniversary was read by Dr. William M. Welch, the chairman. On Saturday evening, January 14th, Dr. J. Chalmers DaCosta will deliver the oration at the College of Physicians, Sunday the 15th, Dr. K. B. Tupper will preach a sermon at the close of which a collection will be taken for the benefit of the Mutual Aid Society, and on Monday the Society will give a dinner at Horticultural Hall to which many prominent men will be invited. As the membership of the Society is now over 700, an unusually large attendance is expected.

Dr. Hughes, president of the Pathological Society, delivered the annual address October 13th. He reviewed the work of the year and complimented the Society upon its success, over one hundred communications with specimens having been presented during the past year. The following officers were elected: President, Dr. W. E. Hughes; vice-presidents, Drs. John Guiteras, F. A. Packard, Alfred Stengel, and Charles W. Burr; secretary, Dr. David Riesman; treasurer, Dr. Thompson S. Westcott; recorder, Dr. D. A. Taylor.

The Philadelphia Red-Cross Society has about completed the necessary alterations to its building at Twentieth and Cherry streets, which is to be opened as a hospital under the direction of Dr. C. P. Franklin, Dr. J. W. O'Neill, W. C. Allison, and a committee of women.

Negotiations were completed last week by which the Samaritan Hospital becomes the possessor of the dwelling next to it, 50 x 230 feet, which is to be added to the hospital as soon as alterations can be made.

The report of the treasurer of the Pennsylvania Training School for Feeble-minded Children at Elwyn shows expenditures of nearly $25,000 during the past year for new buildings and property. There are 890 patients in the institution at present, with room for over one hundred more of the "improvable" class.

Dr. Henry Landis died suddenly at his home in Reading, October 18th. He was formerly President of the Berks County Medical Society, and for many years on the staff of St. Joseph's Hospital.

Dr. Samuel Creadick, a graduate of the University of Pennsylvania, died last week, aged fifty-one. During the municipal campaign of 1896, although he had never before entered politics, the Republicans nominated him for common council to which office he was elected by a large majority.

William S. Leffman, Clerk to the Faculty of the Polyclinic, died October 13th. For a long period of years Mr. Leffman was Clerk at Jefferson Medical College, and many will hear of his death with great regret.

Major Joseph K. Weaver of Norristown succeeds Major Charles Jackson as Surgeon-in-Chief at the Second Division Hospital.

Dr. W. R. Nicholson, Jr., has been elected a member of the staff of the Maternity Hospital to fill the vacancy caused by the death of Major Lawrence S. Smith.

Dr. Clifford Allbutt, Regius Professor of Physic at Cambridge University, recently stopped in Philadelphia, on his way home from California and the East, long enough to deliver two very interesting lectures, the first, "The Pathology of the Circulatory System," at the University of Pennsylvania at the request of Drs. Tyson and Musser; the second, "The Therapeutics of the Circulatory System," at Jefferson Medical College, where he was introduced by Dr. S. Weir Mitchell, who in turn was introduced by Dr. H. A. Hare.

A resolution from the Board of Education was read at the last meeting of the Board of Health complaining that a large percentage of non-vaccinated children are admitted to the schools upon certificates signed without proper evidence. It was resolved to ask the Board of Education for specific cases where the law has been violated so that action may be taken as the law in this respect is very strict.

The total number of deaths occurring in Philadelphia, as reported at the Health Office for the week ending October 22nd, was 389, of which 122 were in children under 5 years of age. The total number of new cases of contagious disease for the week was 218, as follows:

Diphtheria, 104 cases, with 26 deaths; scarlet fever, 20 cases, with 4 deaths; typhoid fever, 94 cases, with 17 deaths.

TRANSACTIONS OF FOREIGN SOCIETIES.

Paris.

PHYSIOLOGICAL EDUCATION OF THE CHARACTER—MARSEILLES AS A SMALLPOX CENTER — TRANSPLANTATION OF LIVING BONE AS A SUPPORT FOR A DEPRESSED NOSE—PERIRECTAL ACTINOMYCOSIS —A CUTANEOUS PYOGENIC INFECTION.

At the Academy of Medicine, September 6th, Ferrand read an article on the "Physiological Education of the Character." He took the position that the character is no more than the *mode of action*, and showed that for the development of the character it is only necessary to excite action in the first place, and then so to organize it that the inferior centers of nervous activity shall remain subordinated to the superior centers until the natural control of these higher centers shall have an opportunity to become firmly established. The speaker added that it is necessary that the inhibitory action of the superior centers over the inferior ones should be an absolute authority, while over them all as a sovereign master should be the intelligent and free will.

Landouzy spoke of the importance of Marseilles as a center for the spread of smallpox. No longer ago than 1886 there were registered there 2400 deaths from this cause. He advocated the isolation of those persons attacked with smallpox, the disinfection of everything contaminated by them, and the vaccination or revaccination of everybody who could be suspected of having had communication with the invalid.

At the session of September 13th, Berger discussed the "Transplantation of Living Bones." Ricard recently reported a case of a young woman into whose back he had grafted a portion of the coccygeal bone of a dog in order to make good the loss occasioned by the removal of a sarcoma. The bone attached itself and was not absorbed, as was proved by palpation five years later. At that time the sarcoma had become general throughout the body, although there was no local recurrence. The experiences of Ollier, Adamkiewicz, and Mosse have shown that such heteroplastic bone grafts are almost always absorbed in whole or in part, but that a fibrous tissue takes their place, so that the desired effect is more or less accomplished after all. The subject is one suited for study with the Röntgen-rays, so that more evidence may be expected upon it. Ricard also reported the case of a woman in whom he had placed a metallic support for a saddle nose. The support caused ulceration of the skin, and had to be removed. The operator then divided the skin in the median line, separating it carefully from the underlying tissues for a considerable distance, and closed it over the fourth metatarsal bone of the patient, which had been removed for that purpose, and suitably shaped. The esthetic result was satisfactory, and the graft maintained its vitality. Nevertheless, in the course of time it lost its bony character, being replaced by a dense fibrous mass, which was sufficiently resisting to prevent the nose from sinking into its former position.

Berger said that metallic supports have been given up by most surgeons on account of their tendency to cause necrosis of the skin. The success obtained by Ricard was gratifying, but by no means a perfect cure since the nose was still short and more or less flattened. Israel had also obtained good results in bone transplantation for this deformity, but after a shorter or longer time the bones were partly or wholly absorbed, with the result that the flattening of the nose was in part reproduced. He agreed with Ricard that autoplastic osseous grafts are no better for this purpose than the bones of an animal.

Poncet narrated the case of a man aged fifty-eight years who had suffered for twenty years from a perineal suppuration complicated by vegetations and ischiorectal indurations, contraction of the sphincter ani, enlargement of the inguinal glands of the right side, etc. For three months he had had pain on micturition, and had passed bloody urine. He admitted when questioned that he had passed a head of wheat into his bladder about a month before the symptoms referable to that organ made their appearance. By means of a lithotrite a hundred fragments of calculus were extracted. The examination of the pus about the anus showed it to contain grains of actinomyces with the central mycelium. The classical treatment by iodid of potash, 4 grams daily, was begun and continued some days without much benefit. A linear proctotomy was, therefore, performed, and from this operation the patient obtained considerable relief in the passage of fecal matter. The granulations were curetted away as far as possible and cauterized. The repair of these lesions went on with great slowness. No more calculi were found in the bladder, but the prostatic urethra still contained phosphatic material. In short, it appeared that the perirectal and perivesical infections had not disappeared, although actinomycotic grains could no longer be found in feces or in the urine.

At the Session of October 4th, Hallopeau spoke of a "Cutaneous Pyogenic Infection" (impetigo herpetiforme d'Hebra). He had recently observed three such cases. The trouble is confined to the skin, and is marked by multiple suppurations of a superficial character, which progressing eccentrically may involve large surfaces of the skin and constantly recur when once healed. They are accompanied by a febrile reaction, which in some patients is intense. The first lesion noticed is a small blister surrounded by an erythematous border. These blisters are multiplied on the margin at the same time that a crust develops in the center. After the removal of the crust a rough and often bleeding surface remains. The lesions are frequently confluent. If the trouble is found upon the limbs it is usually bilateral. The knees are a favorite seat on account of the folds of skin. Besides the skin the mucous membrane of the cheek may become involved, as may also the vagina. The disease may last for months and often terminates in death. It is impossible to say if it is due to the action of modified staphylococci or to some as yet unknown pyogenic microbe. This pyogenic cutaneous infection is distin-

guished from the common pyogenic infection by the absence of infarcts in the viscera, by its duration, which may be very long, and by the possibility of a recovery from it.

SOCIETY PROCEEDINGS.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Abstract of the Proceedings of the Twenty-fourth Annual Meeting, Held at Nashville, Tenn., October 11, 12, 13, and 14, 1898.

(Continued from page 544.)

SECOND DAY—MORNING SESSION.

DR. THOMAS CHARLES MARTIN of Cleveland, Ohio, read a paper, entitled

COMPLETE INSPECTION OF THE RECTUM BY MEANS OF NEWER MECHANICAL CONTRIVANCES.

The newer mechanical means exhibited consisted of a set of proctoscopes which are provided with obturators of peculiar form, of an illumination apparatus susceptible of adjustment to a number of positions, and of an improvement on the Yale chair which facilitates the placing of the patient in the knee-chest posture without requiring any movement on the part of the patient after he is properly seated on the chair. The improvement consists essentially of an upholstered board attached to the left arm of the chair, and a mechanism controlled by a crank and lever, which form a part of the running gear. The anoscope exhibited is an inch and a half (1.27 cm.) in length, and is designed for the inspection of that part of the rectum which is surrounded by the pelvic floor. The proctoscope is four inches (10.16 cm.) long, which the essayist claims is of sufficient length to reach into the inflatable rectum, and is not of so great a length as to obstruct a complete view of the rectal chambers, and yet is of sufficient length to reach the promontory of the sacrum when the pelvic floor is displaced upward by the proctologist's manipulations. Both of these instruments are seven-eighths of an inch (2.22 cm.) in diameter. this diameter having been determined upon as the result of calibration in many normal ani. The average diameter of the instrument is equal to the degree of painless expansibility of the anus. The obturators have contracted necks which constitute these instruments ointment-applicators. The middle part of the obturator is channeled; this qualifies the instrument as a nozzle for rectal irrigation; because of its contracted neck the obturator may be used as a self-retaining nozzle. The surface of each obturator is fluted in such a manner that it may be used as a two-way irrigator when properly fixed within its tube. The technic of the inspection is as follows: The patient is required to sit on the chair with his legs crossed and his body facing the knee-board, which is attached to the left arm of the chair. The chair-back is changed to the horizontal by a movement which puts the patient into the Sims posture. The fixed rectum is now examined by means of a short anoscope. After this portion of the rectum is inspected the chair's lever is extended, its crank turned, and the chair tilted to such an extreme degree of the oblique lateral position that the chair-seat is almost perpendicular and the knee-piece, which is a part of the left arm of the chair and against which the patient's knees are pressing, is almost horizontal. Now, at a time when the patient is resting easily in a position which is equivalent to the knee-chest posture, the anoscope is introduced, the obturator withdrawn, and the inspection of the ballooned gut completed. The patient is passively returned to his feet by executing in the reverse order the several steps of this procedure.

THE RELATION BETWEEN THE GENITO-URINARY TRACT AND RECTUM; IN OPERATIONS UPON THE FEMALE, WHICH SHOULD RECEIVE PRIORITY?

This paper was read by DR. JOHN L. JELKS of Memphis. The author champions the assertion that the gynecologist should be as well prepared to remove hemorrhoids and treat an ulcerated rectum as to dissect a cicatrix from the cervix or repair a perineum. The rectal surgeon often finds that although the rectum is involved to such an extent as to be chiefly complained of the chief source of danger to the patient is a pus-tube or some other disease. In other words, to relieve the patient and restore her to health and happiness, he must also dissect from the cervix uteri a cicatrix and repair a lacerated perineum. In another case he may be required to sever a urethral stricture.

DR. WILLIAM B. BRUNS of Deckerville, Ark., read a paper, entitled

RECTAL FISTULA IN THE CAUSATION OF ISCHIORECTAL ABSCESS,

in which he reported a case with two large pus-pockets. He opened the abscess, emptied its cavity, and subsequently did an operation for the removal of the fistula.

DR. GEORGE D. KAHLO of Indianapolis followed with a contribution on

HYDROTHERAPY IN STOMACH DISEASES.

He said that water is essential to the performance of all physiological functions; yet its importance as a remedial agent is not so generally recognized. While he does not wish to be understood as opposing entirely the use of drugs in diseases of the stomach, he desired to say that he believes water ranks first among therapeutical resources. It may be used internally as a drink, in lavage, as a douche, and as a spray, and externally either applied locally or generally. Its effects, when administered internally, depend upon the conditions of the stomach in respect both to taking of food and whether or not there is normal digestion, as also upon the amount and temperature of the water ingested. Cold applications of all kinds are antiphlogistic, and when prolonged are sedative. They are indicated in acute gastritis and in the control of vomiting and hematemesis, but to obtain their full effect it is necessary that their local condition produce an active hyperemia of the skin. Hot applications are useful in the treatment of gastralgia, hyperesthesia, gastric ulcer, and chronic gastritis. While he does not ignore the beneficial influence of such agencies as diet, exercise, massage, and electricity, not to speak of a few of the more

important drugs which are thus used, and in obstinate cases especially, physicians are not likely to rely wholly upon any one remedy, however valuable. To be successful, hydrotherapy, like all other forms of treatment, has for its governing factors an exact diagnosis, a thorough knowledge of the patient, a full understanding of the causative influence and a clear conception of the effects of the remedial agent. To this must be added the confidence and cooperation of the patient.

Afternoon Session.

Dr. Thomas Hunt Stucky of Louisville read a paper on

Auto-intoxication of intestinal origin.

Dr. Edwin F. Wilson of Columbus, Ohio, read a

Clinical report of a case of abscess of the liver.

In referring to the clinical aspects of abscess of the liver, he called attention to the essentials in diagnosis, and dwelt upon the history of the disease. He reported three cases. Of these the diagnosis was confirmed in two by post-mortem; in the other by aspiration. In all three the abscesses were chronic when they came under his observation. In only one of the cases was there a history of dysentery, although in one case scars of healed ulcers were found in the large intestine. In these cases he finds the enlargement of the liver is upward. Hoover has made a diagnosis of abscess of the liver from a friction sound in the axillary line between the eighth and tenth ribs. The essayist has not heard this sound in any of his cases, but this should be borne in mind when making an examination in this region. Two of the cases reported were mistaken for malaria. This mistake can be avoided by the more general use of blood examinations. The absence of the plasmodium would settle this at once.

Dr. J. C. Morfit of St. Louis, Mo., read a paper on

The importance of early diagnosis in surgical cases.

The diagnosis of a disease ought to be the most attractive feature in the practice of medicine or surgery. It is the foundation on which any plan of treatment is applied. The physician should promptly and exhaustively weigh every indication of cause and effect and apply his therapy accordingly. He has recently seen two cases of pyosalpinx which were cured by surgical interference. Both had been treated by good practitioners, yet neither had made a complete physical examination, and consequently the real trouble was not detected. One patient was treated for indefinite inflammation of the bowels, the other for malaria. He cited these cases to emphasize the duty of the physician to himself and his patients of utilizing every available means to arrive at an early and positive decision as to what he is treating.

Gonangiectomy and orchidectomy for hypertrophied prostate in the aged.

An excellent paper on this subject was read by Dr. George W. Johnson of Dunning, Ill., in which he reported five cases, and made a second report on twenty-eight cases previously recorded.

After referring at length to the literature of the subject and reporting his cases in detail, Dr. Johnson arrived at the following conclusions: (1) All cases of prostatic hypertrophy should be given at least two weeks of palliative treatment, with rest in bed. This treatment should be regulated according to the conditions. (2) If no relief is had from this line of treatment, a thorough and systematic examination should be made for vesical calculi and polypi, as well as structural and malignant disease of the prostate and bladder. Cystitis, acute prostatitis, and prostatic abscess, should always be borne in mind. The urine should be frequently examined. In cases of cystitis the ureters should be catheterized to determine the condition of the kidneys. This can now be easily done by the Harris instrument. If by digital examination per rectum the prostate is found to be enlarged its approximate dimensions should be noted and urethral measurements taken. The patient should then be as well prepared as possible for operation. Having decided upon operative interference, the operator alone must decide upon what operation he will do. Gonangiectomy or orchidectomy offers less risk to life. (3) Chloroform should be used, as it requires less time and is not so irritating to the kidneys. The operation should consume as little time as possible. Gonangiectomy or orchidectomy can be done quicker and with less shock than any other operation. Strict attention should be given to the after-treatment. (4) The time for relief after operation is irregular. In his experience the relief has not been as clearly defined as to hours and days, nor as immediate as in most cases reported. In but two cases has the catheter been required after operation. Enuresis was constantly present in his cases for from one to six weeks after operation. (5) More immediate relief is given to cases of orchidectomy, and the prostate softens and diminishes more rapidly in such cases than where gonangiectomy is done. (6) The kidneys should be carefully watched and supported after operation. Mental symptoms appeared in three of his cases, two of which were due to renal disease. (7) Long-standing and troublesome herniæ can be successfully treated in the aged. He has successfully treated eighty-four such cases, in none of which has a recurrence taken place up this time. Of this number he has encountered the condition of congenital with acquired hernia in six cases. In five of the cases the acquired sac was outside of the congenital one. In one case it was within it. (8) Bassini's operation was resorted to in all but five cases, and in these Fowler's method was used. (9) Cystic degeneration of the testicles was met with in twenty-five cases. These usually had chronic hydrocele also, and were always cases with hernia of long duration. (10) When the intestines occupied the scrotum in large mass, they were returned to the abdominal cavity three or four days before the operation. In many cases there were adhesions preventing reduction. (11) Examinations were always made for vesical calculus, but none found. (12) The somatic condition is greatly improved, and when bilateral orchi-

dectomy was done, the patients became obese. (13) A thorough line of palliative treatment of from two to six-weeks' duration, with rest in bed, was given each patient. (14) In cases of herniotomy the patient was kept in bed from three to five weeks, unless very asthenic, with the hope of getting better organic union and thereby minimizing liability to recurrence.

THIRD DAY—MORNING SESSION.

DR. GEORGE BEN JOHNSTON of Richmond, Virginia, delivered the address on surgery.

His subject was

THE PROGRESS OF RENAL SURGERY.

Renal surgery is altogether a matter of the past three decades, having had its commencement with the successful nephrectomy performed by Simon in 1869. Dr. Johnston dealt with nephrotomy, floating and movable kidney, renal and ureteral calculi, neoplasms of the kidney, tuberculosis of the kidney, when not a part of a general miliary tuberculosis, which he said may either have its origin in the kidney, or may be an ascending affection from the bladder. Hydronephrosis also received attention. He made no attempt to arrive with anything approaching completeness at the progress or present status of surgery of the kidney. He endeavored merely to point out some of the advances which have been made in this field of surgery, and to indicate the present views of surgeons upon some of the most important points. Especially did he emphasize the conservatism which has developed along this line, and which now marks the attitude of the surgeon in this as in other branches — a conservatism which realizes that the glory of surgery is not in amputation and in mutilation, but in saving important organs.

WHY I PERFORM VAGINAL ABLATION IN PELVIC INFLAMMATORY CASES.

By DR. WILLIAM R. PRYOR of New York City. He stated why, when he performs hysterectomy in pus cases, he prefers the vaginal route. He dealt with the subject under the respective heads: Incision; separation of adhesions; direction of effort in the enucleation; hemostasis; drainage; hernia; accidents; instruments; narcosis and time; convalescence, and results.

Up to October 1st, of this year he has performed vaginal hysterectomy for pelvic inflammatory lesions, exclusive of fibroids and cancer, eighty times. Since that time he has performed the operation a number of times. No patient has died either from the operation or from complications. He has no fecal fistulæ to report, no sinuses, no vesicovaginal fistulæ, and no hernias. There have been no cases of phlebitis and no intestinal obstructions. The vagina has in no case been shortened. For the technic of the operation he refers the reader to the *American Journal of Obstetrics*, volume xxxviii, No. 6, 1898.

A CONSIDERATION OF THE LIMIT TO OPERATIVE GYNECOLOGY.

By DR. SHELBY C. CARSON of Greensboro, Ala. The purpose of this paper was to emphasize the importance of medical gynecology; to show that surgery cannot advance a legitimate claim to even the larger portion of this great field. A beautiful tribute was paid to this branch of medicine by applying to it the eloquent eulogy of Daniel Webster upon justice. Surgery as a science is pronounced as practically without limit, but as an art it has probably reached the summit. What constitutes true surgery was then discussed, the author quoting not only from text-books, but from the latest utterances of such men as Wyeth and Annandale, proving that surgery, of all branches, is based upon principles, and hedged in by fixed laws; that when these are disregarded there is no true surgery. The folly of the ablation of the ovaries and tubes in many cases was made manifest. The nerve element in women was closely considered, the anatomical connection between the nervous system and the genitalia being defined. As a consequence, neurasthenia is a frequent result, for which surgery affords no relief.

THE THERAPEUTIC VALUE OF LEAVING LARGE QUANTITIES OF NORMAL SALT SOLUTION IN THE ABDOMEN.

The author of this paper was DR. J. WESLEY BOVEE of Washington, D. C. He reported six cases to illustrate the usefulness of this procedure. In a number of cases the effect was not so marked, and in a few but little benefit was apparent. The first case was one of papillomatous broad ligament cyst; fifteen liters of normal salt solution left in abdomen; marked increase in urine. Case II. Large multiple uterine fibroma, and large ventral hernia; secondary operation; three liters normal salt solution in abdominal cavity, and one liter under breast, with marked urinary increase. Case III. Papillomatous fibro-adeno-cystoma of right broad ligament; eight liters normal salt solution left in abdomen; considerable urinary increase. Case IV. Multilocular ovarian cyst; 5000 c.c. normal salt solution left in abdomen; increased excretion of urine. Case V. Multiple fibroma of the uterus and pelvic adhesions; great shock; two liters of normal salt solution left in abdomen; increased urinary excretion. Case VI. Multilocular cartilagino-cystoma of left ovary; seven liters normal salt solution left in abdomen; excretion nearly doubled during the following six days.

The marked stimulating effect of the remedy on the kidneys was noticeable in all these cases. Penrose has found that the average amount of urine excreted during the first twenty-four hours after operation in 100 cases was 13.4 ounces; for the second, 14.6 ounces, and for the third, 19.8 ounces. He also found that for the first day the maximum amount of urine was 27 ounces. In many of the cases of the essayist this maximum was much more than doubled. While the number of cases in which he has used these large quantities of normal salt solution is small, the effect should encourage a further application of the remedy in proper cases. Not one evil result of the solution was observed in any of the cases.

DR. F. F. BRYAN of Georgetown, Ky., read a paper, entitled

A PLEA FOR PELVIC CELLULITIS AND PERITONITIS.

He reported twenty cases and drew the following conclusions: (1) Cellulitis and peritonitis are important manifestations leading to the greatest amount of suffering

that woman is heir to. (2) Their recognition and the retention of their nomenclature should keep physicians constantly on the watch for them. (3) Their proper treatment in the early stages will obviate these latter evils to a great extent, as cellulitis and peritonitis are easily curable in the early acute stages. (4) That should opportunity for an early cure not be offered, then the chronic cases should have the medical and minor gynecological treatment mentioned by him, under which many will be cured, others obtain relief, and a respectable quota will of necessity have to turn to surgery for their cure.

Afternoon Session.

SURGICAL TREATMENT OF PARALYSIS IN CHILDREN.

Dr. Alex. C. Wiener of Chicago read this paper. A clear distinction should be made in diagnosis as well as treatment between cerebral and spinal paralysis. A common symptom in both diseases is paralysis, and yet there is a great difference between the two affections. In spastic paralysis one group of muscles becomes rigid and overpowers its opponents, rendering them overstretched and useless, but still their innervation is by no means disturbed. In spinal paralysis there is a true degeneration of the lower neuron and the dependent muscular groups. This being borne in mind, the treatment is to equalize the balance between the spastic and the overstretched muscular group by lengthening the rigid muscles. This is done either by tenotomy, resection of tendons, or loosening the attachments of the muscles from the bone as is done in a spastic condition of the adductor muscles of the pelvis. The after-treatment consists mainly in not allowing the extremity to leave its over-corrected position too soon, and in strengthening the functionally weakened opponents by massage, baths, and electricity. Apparatus in these cases is utterly useless and should be entirely discarded. Any other peripheral cause of reflex irritation, as phimosis, occlusion of the prepuce, or of the clitoris, of course is to be removed. In anterior poliomyelitis we have to deal with a true paralysis of certain muscular groups. This may be overcome by apparatus which supplants the paralyzed muscles, or by operative procedures. This consists in dividing the belly of an active muscle up to the place of its insertion and sewing the corresponding part of the tendon into the cleft of the tendon which belongs to the paralyzed muscle. The inactive muscle is supplied with the vigor of the innervated muscle, taking care, as Milliken has pointed out, that the sheath of the tendon is preserved. By this artificial change in the arrangement of muscles the function of one muscle is transmitted to another. There is taking place an alteration of the reflex activity in the nerve-centers of the muscles; hence, the importance of the function of the extremity is by no means a mere mechanical act.

THE DIAGNOSIS OF GONORRHEA IN WOMEN.

By Joseph Rilus Eastman of Indianapolis. The diagnosis of this affection in women is comparatively easy, even without the microscope. With a history of impure coitus, free purulent secretion from the vulva, vagina, and urethra; intertrigo, burning on micturition, and vesical tenesmus, the diagnosis is not far to seek. Upon inspection one usually detects a discharge of tenacious pus, or greenish or yellowish streaks upon the linen may alone be in evidence. The symptoms of gonorrhea in women were dwelt upon at great length.

The gonococcus grows fat upon flat epithelium. A comprehensive examination of the discharge is not complete until the secretions of the urethra, Skene's lacunæ, the glands of Bartholin, the vagina and cervix have been searched through; and in chronic cases several preparations should be made from each of these. To secure unmixed gonorrheal pus from the cervix uteri care should be taken that the platinum wire does not come in contact with the vagina. It is best to first rinse and then dry the vagina with cotton to free it from mucus.

It will be concluded after many examinations for gonococci that the urethra is the seat of predilection of gonorrhea in women, and that the vulvitis and vaginitis are secondary, being caused by the bathing of these parts with the discharge from the urethra and cervix. The diagnosis of acute gonorrhea may be made by contemplation of the clinical phenomena alone. For example, if acute urethritis be present, it is almost certain that the gonococcus is to blame. Observation for a few days will establish the diagnosis beyond conjecture, since the symptoms of non-specific urethritis will disappear rapidly. In chronic gonorrhea too much dependence upon clinical manifestations is hazardous. Condylomata are often present, but appear also often independently of gonorrhea. Débris-laden discharge from the vulvovaginal glands is usually an expression of old gonorrhea, but other germs, as the staphylococcus aureus and saprophytic forms may occasion just such discharge. Among the more common indications of chronic gonorrhea are the maculæ gonorrhoicæ of Sanger, red papules about the openings of the vulvovaginal glands, sclerotic inflammation of these glands, in which the glands are felt as hard, non-sensitive nodules under the examining finger, cysts of these glands, and scars and erosions in the vulva. All of these conditions may be caused by other germs than gonococci. Here, as in acute gonorrhea, the most reliable indication is the urethritis.

POSTERIOR DISPLACEMENTS OF THE UTERUS.

Dr. A. M. Cartledge of Louisville read this paper, in which he dealt with the subject from a clinical standpoint. He discussed the causes, symptoms, and diagnosis of these displacements.

Treatment should be divided into measures which correct the cause and methods of support by suturing and shortening the round ligaments. Sometimes it is necessary to employ both methods in the same individual in order to make the result durable. In the first category are to be included thorough curettage; repair of cervical lacerations, if present; perineorrhaphy and restoration of the pelvic floor; tonics, laxatives, and rest. These methods, if carried out successfully, will ultimately relieve the vast majority of posterior displacements. They are not so dramatic or sudden in their relief as ventrofixation and Alexander's operation, but are more in accord with ra-

tional ideas. In order to succeed they require time—six to eight months for the structures to resume their normal tone. They also usually require to be supplemented during some weeks or months following their performance by anterior and posterior tamponade, or a well-fitting pessary to hold the uterus in position until the repaired parts regain their strength. It is irrational surgery to use any form of support until existing causes have been as far as possible removed.

As between ventrofixation, vaginofixation, and Alexander's operation, preference should be given the latter, if no accompanying disease is suspected. Where such disease exists, the operation of ventrofixation should be practised, as it gives opportunity for inspection and correction of the pelvic disease. It is the best operation in all cases of adherent uteri.

Dr. A. H. Cordier of Kansas City, Missouri, followed with a paper, entitled

SOME PHASES OF INTESTINAL OBSTRUCTION.

The causes of this condition are many and varied. Modern methods of diagnosis in skilled hands have led to the saving of many lives, which, heretofore, would have been lost by delay in resorting to the proper treatment. While the diagnosis of intestinal obstruction can usually be made early, there are some cases in which the pathological manifestations are so insidious or vague that their detection requires time and much careful clinical analysis. The symptoms of intestinal obstruction were thoroughly outlined. He said the falsehoods uttered by pain and the truths untold by opium have been very expensive to human life in the management of intestinal obstruction.

Surgical treatment for the relief of this condition should be resorted to early. It should be thorough and quick. No protracted delays or chronic surgery should enter into the management of an acute intestinal strangulation, as these patients stand prolonged anesthesia and slow surgery badly.

Dr. F. F. Lawrence of Columbus, Ohio, followed with a contribution, entitled

ESSENTIALS TO SUCCESS IN ABDOMINAL SURGERY.

Dr. Bayard Holmes of Chicago read a very interesting paper, entitled

THE SURGICAL TREATMENT OF EXOPHTHALMIC GOITER.

He said the surgical treatment is based on the theory that in this disease the direct morbid factor is an increase in the normal excretion of the thyroid gland. He gave a synopsis of the physiology and pathology, and an outline of the embryology of the thyroid, after which he reported a case upon which he had operated, which was a very powerful argument in favor of surgery in dealing with this affection.

SOME FORMS OF GANGRENE AND THEIR TREATMENT.

By Dr. J. S. Nowlin of Shelbyville, Tenn. Gangrene means death of a part, and is applied to the soft tissues. The blood is always involved in this disease. If the blood is performing its functions there can be no local death. The blood-channels being destroyed, gangrene necessarily follows. Gangrene appears sometimes suddenly after injuries to the spinal cord. A normal functional activity in the blood prevents the first step in the process of inflammation. Simple endarteritis may be the cause of gangrene; an inflamed artery is then surcharged with blood, stasis results, coagulation takes place, the lumen is destroyed to a certain extent, and gangrene results. Sepsis is doubtless a most frequent cause of gangrene in the extremities. In traumatic gangrene the surgeon should look out for sepsis. If there be a simple endarteritis with tissue formation amputation should be performed at the first evidence of failing vitality.

Fourth Day—Morning Session.

Dr. A. M. Osness of Dayton, Ohio, contributed a paper on

DIPHTHERIA AND ITS LOCAL TREATMENT.

He said the pathological process in diphtheria is caused by the serum albumin at the point of infection becoming moderated from incorporation with the specific virus. It is then repudiated by the blood-stream and exudes into the neighboring tissues, where it, plus necrotic cells and fibrin, forms the pseudo-membrane, that is, a congenial nidus for the Klebs-Loeffler bacillus. The intoxication of the system depends upon the energy of the lymphatics upon which devolves the removal of the exudate. In the treatment the use of antitoxin serum offers the risk of over-toxicity, from additional toxin or systemic impairment from invalidation of the centers; while monosulphid of calcium has been given in ¼-grain doses every half hour for a period of thirty-six hours to children with the best of results. Water should be taken internally quite freely to help elimination of the toxin, local swabbing being resorted to as well, with a mixture such as the physician deems necessary.

Dr. William K. Jaques of Chicago followed with an excellent contribution on

THE EARLY DIAGNOSIS OF DIPHTHERIA.

He said that outside of laryngeal complications the mortality from diphtheria is due to the toxin produced by the Klebs-Loeffler bacilli. No physician can successfully treat diphtheria unless he understands the nature of this toxin, how it is produced, and how the cells may be fortified against its destructive action. He must understand that the Klebs-Loeffler bacillus is a distinct living entity, or vegetable organism; that one of the products of its existence is diphtheria toxin, just as the result of the life of the yeast plant is alcohol. To appreciate the danger of his patient a physician must understand the rapidity with which these bacilli multiply under favorable conditions. The clinical symptoms manifesting their residence may give no indication as to the rapidity with which the fatal amount of toxin is being produced. Understanding that toxin is a product of these germs, their multiplication means an increased amount of toxin which soon reaches the fatal point unless checked by the use of antitoxin. This demonstrates the importance of a physician knowing

at the earliest possible moment what germs are present in an angina.

In order to ascertain the value of direct diagnosis, by which is meant the examination of material taken directly from the infected area without waiting for incubation, the Chicago Health Department has introduced the following culture outfit for the use of physicians: A sterilized swab is placed in a glass tube; a slide carefully wrapped in paper is placed with this in an envelope together with a culture-box and directions for using the same. Physicians are requested to inoculate the swab from the inflamed site, spread a little of the mucus upon the slide and allow it to dry. The culture medium is inoculated from the same swab and it is returned to the glass tube. The whole outfit is then to be sent to the nearest incubator station or laboratory.

When no antiseptic treatment has been administered before the culture is taken, and the disease manifests malignancy by stupor, hoarseness, or swelling of the cervical glands, it has been possible in about fifty per cent. of the cases to find sufficient bacilli to warrant a diagnosis of diphtheria even before any trace of membrane is visible. When it has been possible to get a small portion of membrane to spread on the slide, there has been no difficulty whatever in about seventy-five per cent. of the cases in making a direct diagnosis.

In the malignant form of diphtheria nearly fifty per cent. of the patients die unless proper treatment is administered. Any physician who neglects to make a correct diagnosis during the time when the remedy is efficacious, that is, during the first two or three days, is responsible for the result.

The technic of bacterial diagnosis of diphtheria is simple. The entire outfit for this work may be obtained for less than $100. The essentials may be acquired at home by any physician who is willing to devote no more than his leisure moments to it.

To demonstrate the protective value of antitoxin the following experiment has been conducted: On October 10th, in the presence of Dr. F. W. Reilly, Assistant Health Commissioner of Chicago; Dr. Wynekoop, Assistant Bacteriologist, the essayist, and Dr. Adolph Gehrmann, nine guinea-pigs were injected with four times fatal doses of diphtheria toxin. The first three were immunized two days previously by the injection of 0.1 c. c. each of Parke, Davis & Co.'s antitoxin. The next three received 0.5 c. c. of the same antitoxin each, following the injection of toxin. The third three have had no treatment whatever since the injection of the toxin. The pigs were correctly labeled as to condition, and presented decided effects upon the fourth day. All pigs that received antitoxin are alive and apparently well. Of the three not protected two are dead. The third being still alive, would indicate the possession of natural immunity against the toxin.

Dr. H. W. Whittaker of Columbus, Ohio read a paper on

PICHI.

In Chili, South America, pichi is found growing as a shrub in abundance. No doubt the active principle of the drug resides in the balsamic resin, but chemical examinations have so far been unsatisfactory in determining its chemical composition.

The annoying symptoms of chronic cystitis with enlarged prostate yield to the action of pichi, as was illustrated by the citation of a case. Cystitis complicating specific urethral infection, involving the prostatic urethra, is a combination which under favorable circumstances does not readily respond to treatment, and yet under the influence of this drug the conditions become more tolerable. This remedy is indicated in all of the various forms of diseases of the liver. In gall-stones pichi has proven a valuable remedy in assisting the secretion of bile and theoretically aiding the discharge of the stones. Uric-acid formations rapidly disappear from the urine under the corrective influence of this remedy and the general condition of the patient improves.

Dr. J. Henry Carstens of Detroit reported a case of rupture of the body of the uterus during confinement.

A FEW PRACTICAL POINTS IN THE TREATMENT OF POSTERIOR URETHRITIS.

This paper was read by Dr. A. Ravogli of Cincinnati, Ohio. The author recapitulated the principles of the treatment for this disease as (1) irrigations by the Janet method in a recent case of gonorrhea will in many cases prevent posterior urethritis. (2) Irrigation with the recurrent catheter with permanganate of potassium, followed by injections of protargol, will cure in a relatively short time a case of subacute posterior urethritis without complications. (3) When chronic posterior urethritis lasts for a long time, and has caused infiltration of the submucous tissues, then the application of a sound with ichthyol salve gives the best results.

Dr. F. E. Kelly of Lamoille, Ill., read a paper on

VARICOCELE.

The author outlined the operation for radical cure and the indications for its performance. He considers Bennett's operation of resection of the veins and shortening of the spermatic cord the ideal radical procedure, which he described in detail.

Dr. R. A. Bate of Louisville read a paper, entitled

THE ARTHRITIC DIATHESIS.

The term diathesis is applied to an inherited predisposition to altered nutrition. He assumed in diathesis an inability on the part of the cells to produce oxidation. He mentioned the diseases generally conceded to be dependent upon the arthritic diathesis. He has experienced favorable results from antilithemic remedies in glycosuria, nasal and bronchial asthma, lithiasis, albuminuria, obesity, eczema, paresis, rheumatism, angina pectoris, recurrent typhlitis, vertigo, biliousness, dyspepsia, neuralgia, and migraine.

Dr. Albert E. Sterne of Indianapolis contributed a paper, entitled

A TRIOLOGY OF DISEASES: ACUTE ARTICULAR RHEUMATISM, ENDOCARDITIS, AND CHOREA.

He advanced considerations concerning the nature of these three affections and of the connection of chorea with

manifestly infectious disease, namely, acute articular rheumatism. A case was reported in point. While he could report several instances of chorea associated with both arthritis and heart lesions, this is the only case known to him where the sequence of this triology seemed distinctly connected with a suppurating injury, following a fairly incontestable portal to the invasion of the ordinary pus-microbes to the system. If it be admitted that valvular disease is mainly rheumatic, or at least infectious in character, then the list of cases of chorea connected with the diathesis becomes much greater, inasmuch as from twenty-five to fifty per cent. (Osler) of cardiac patients give a history of chorea. Looking at the question impartially, it seems almost imperative to assume an intimate relationship between the three diseases.

The following preamble and resolutions were offered and unanimously adopted:

WHEREAS, The general public, the medical profession, and the drug trade of the United States have long suffered extortion at the hands of foreign manufacturers of synthetic remedies, and

WHEREAS, Our lax and indulgent patent laws bestow a triple monopoly upon the process, the composition and the name of chemical products for medicinal use, thus excluding every possibility of a healthy competition; and

WHEREAS, The same evil has been recently disclosed in the domain of biological medicine by the patent granted Professor Emil Behring and the Hoechst Farbwerke on antidiphtheritic serum, a patent which could not be obtained in Germany, France, England, or Canada; therefore,

Be It Resolved, by the Mississippi Valley Medical Association, that the seal of its condemnation be placed upon the unethical and unprofessional conduct of Professor Behring; that it is the duty of every member to renounce the use of the Behring serum; and that the American manufacturers who purpose contesting the patent in the courts are entitled to the moral and substantial support of every American practitioner.

Resolved, That an earnest appeal be made to the members of the Commission on the revision of our patent and trademark laws, appointed by President McKinley, and their assistance invoked for the modification of existing laws and the suppression of prevailing abuses.

Resolved, That a copy of these resolutions be sent to every medical journal in the United States and to the members of said Commission, as follows: Hon. Arthur P. Greely, Assistant Commissioner of Patents, Washington, D. C.; Hon. Peter Grosscup, Chicago, and Mr. Francis Forbes, New York city.

Resolved, That the members of this Society be urged to write their Congressional representatives at Washington and bespeak their support of any measures of relief ultimately proposed by the Commission.

The following officers were elected for the ensuing year: President, Dr. Duncan Eve, Nashville; first vice-president, Dr. A. J. Ochsner, Chicago; second vice-president, Dr. J. C. Morfit, St. Louis; secretary, Dr. Henry E. Tuley, Louisville, re-elected; treasurer, Dr. Dudley S. Reynolds, Louisville, re-elected. Chicago was selected as the place for holding the next meeting, the time of which is to be fixed by the Committee of Arrangements and the executive officers.

NEW YORK STATE MEDICAL ASSOCIATION.

Fifteenth Annual Meeting. Held in Mott Memorial Hall, New York City, October 18, 19, and 20, 1898.

FIRST DAY—MORNING SESSION.

THE meeting was called to order by the President, DR. DOUGLAS AYRES of Montgomery County. An address of welcome was delivered by DR. FREDERICK HOLME WIGGIN of New York, Chairman of the Committee of Arrangements. The treasurer's report, read by the secretary, DR. E. D. FERGUSON of Rensselaer County, showed a balance in the hands of the treasurer of $4895.75. Despite the fact that $2000 was contributed to the Rush Monument Fund during the present year, the amount on hand is only $1622 less than it was last year.

DR. WIGGIN then reported the result of the effort of the committee appointed at the last meeting to secure proper legislation for the regulation of dispensaries and the prevention of the abuse of medical charities. He detailed the differences between the bill introduced into the Legislature in 1898 and the Sullivan bill that had been vetoed by the Governor in 1897. He recounted how, though the Senate had passed the bill thus modified with but two dissenting votes, it had been killed in the Assembly committee despite the strenuous efforts of the united committees of the various medical societies, and suggested the appointment of a new committee to carry on the work, which practically every one is agreed is so absolutely necessary. He insisted that there is no effort being made to curtail medical charities, but on the contrary, the intention is to increase true charity and make it possible to aid more efficiently the worthy objects of such charity by eliminating from the number of those applying for free medical relief all those found on investigation to be undeserving of it.

To the question as to what arguments had been brought forward that had prevented the passage of the bill through the Assembly committee, Dr. Wiggin replied that there had been practically none, and certainly none that had been deemed of any weight by the Senate committee, though the same set of arguments opposing the bill were presented to both committees.

DR. WICKES WASHBURN of New York begged to supplement Dr. Wiggin's statement to this extent: "Members of the Senate committee had stated that if the committee in opposition to the bill had no further arguments to present than those they brought before them their presence was calculated to hurt rather than help their cause."

DR. DOUGLAS AYRES then read the President's Address,

A RESUME OF MEDICAL AND SURGICAL PROGRESS.

He detailed the striking advances that have been made in all departments of medical science during this last half century, and dwelt upon the fact that the surest and easiest way to keep abreast of medical progress is to be thor-

oughly interested in the proceedings of medical societies, actively as a contributor, passively as an interested attendant at their sessions, and hoped that the present meeting of the New York State Medical Association would fulfil the promise of its predecessors and the hopes of interested members.

Dr. J. G. Hunt of Oneida County read the first paper on the program, entitled

CONSERVATIVE SURGERY IN CRUSHING INJURIES.

He considers that the striking advance in modern surgery since the introduction of antisepsis has been in the line of even greater conservatism in the treatment of injured limbs. He thinks that the limits of this conservatism have not been reached and that limbs are sometimes sacrificed even yet that might be saved. He illustrated by a case and by statistics from his practice among railroad employees, and mill and factory hands, that conservatism must be the keynote of modern surgical practice in the treatment of the injuries of this class of people even as regards the smallest member.

Dr. Overton of Suffolk County read a paper on

THE TEACHING OF PHYSIOLOGY AND HYGIENE IN THE PUBLIC SCHOOLS.

He considers that our best hope that the people will sooner or later have some standard by which to distinguish the mere money-making quack from the serious physician, is founded in a practical knowledge of the elementary principles of physiology and hygiene to be obtained at our public schools. How important this matter is for the people may be gathered from the extent to which the advertised remedies and the advertising quacks have invaded all advertising media. The present teaching does something toward securing a practical knowledge of physiology and hygiene, the only one that can do any good, but falls far short of what might be accomplished. There is danger of the pupils merely learning a series of thoroughly misunderstood scientific terms rather than acquiring any practical scientific knowledge. It is unfortunate, too, that so much weight is laid by existing laws upon the teaching of the effects of but one form of abuse upon the organism. There is, perhaps, some compensatory advantage in the fact that a well-grounded knowledge of one form of abuse will more easily lead on reflection to a realization of the results of other abuses also.

A practical knowledge of physiology could be best imparted by a series of simple experiments on animals, cold-blooded ones as the frog, for instance, being preferably employed. Simple demonstrations of such things as the circulation could be easily made this way in a manner that would never be forgotten. The compound microscopes, one of which every school is bound by law to have, should be brought into use, and the facts and principles of cellular life, the important groundwork of all physiology, made the subject of actual demonstration.

Dr. Delancey Rochester of Erie County, in the discussion said he thought that something of the significance of venereal diseases should be taught at least to older pupils just before leaving school. The ignorance on this subject, fostered by a prudish prejudice in the matter, is the source of a great deal of physical evil to young people just entering life. Knowledge of these subjects instead of adding to pruriency would form an additional safeguard to morals and the best possible adjuvant factor for protection in temptation. The significance of venereal disease is known to be very different now to what it had been in the past, and it is too bad that this knowledge is not more widespread.

Dr. Overton, in closing the discussion, said that publishers of school text-books who are presumed, at least, to know what is or is not salable, absolutely refuse to allow even the slightest passing reference to such subjects.

Dr. Stephen Smith of New York read a paper on

A NEW METHOD OF AMPUTATION AT THE KNEE-JOINT APPLICABLE TO CASES OF SENILE GANGRENE OF THE FOOT.

Dr. Smith had devised his operation for a patient aged seventy-eight, with acoholic history and extremely rigid arteries, whose large toe was gangrenous. There were dusky spots around the ankle, and an enfeebled circulation in the foot and leg. Instead of adopting the high operation above the knee that has been recommended by so many American and English surgeons, and lately again by Mr. Jonathan Hutchinson, he studied the circulation to the knee, and planned his incisions so as to cut as few main branches of arteries as possible. The blood-supply to the soft tissues in the region of the knee is very copious, and by this operation none of it is interfered with. His directions are: "Make a straight incision, commencing two inches above the upper border of the patella downward over the center of that bone to the tuberosity of the tibia. From the lower extremity of this make two curved incisions, the convexity of each being downward, one to the external, the other to the internal border of the leg. Join these two incisions posteriorily by a straight incision across the upper border of the calf. Dissect these two flaps from the tibia and fibula, remove patella, and disarticulate the tibia." He secured union by first intention in his case.

Dr. Gouley, in the discussion which followed, said that some cases of senile gangrene do well with amputation at the knee-joint, but many require amputation higher up. He had seen a case in which the thrombus occupied the upper third of the femoral, when, of course, even amputation above the knee, unless at an unusual height, would have failed.

Dr. Cleaver of Reading, Pa., asked Dr. Smith how hemorrhage had been controlled during the amputation, and Dr. Smith explained that it was by digital pressure, the delicate sclerosed arteries being protected from possible injury even from pressure of the fingers by a pad.

Dr. Gouley said the Esmarch bandage is always contraindicated in these cases because of the danger of injuring the arteries.

Dr. Leroy J. Brooks of Chenango County then read a paper, entitled

SUBNORMAL TEMPERATURE.

Though the significance of this condition has not at-

tracted much attention, he considers it quite as important as supranormal temperature. All persistent subnormal temperatures he thinks pathological, despite the fact that a certain number of cases have been reported where this phenomenon existed in supposedly healthy people. The subnormal temperature is especially prone to precede and give warning of certain serious conditions. It has preceded in his experience in a number of cases the development of neurasthenia and hysteria. It was sometimes a prodrome of impending mental disturbance, physical and mental depression being coordinate. He noted it as an important index of approaching mental trouble in two members of a family, seven of whom had committed suicide by hanging.

He has noted it in dipsomaniacs just before an outbreak of their trouble. It constitutes in these cases a most significant index of the intense state of physical depression that supervenes, and finally drives the patient inevitably to the taking of stimulants to excess. In a certain number of cases subnormal temperature would seem to be the expression of a deficient circulation, due to hypoplasia of heart and blood-vessels, the heart especially being too small for the body, and then the subnormal temperature persists.

DR. DELANCEY ROCHESTER had seen subnormal temperatures in cases in which the heart seemed to have been too large for the body—in athletes, bicyclists, and football players. The subnormal temperatures were noted at times when the men had not been overexerting themselves, and seemed the expression of circulatory disturbance. He had found the excretions deficient in these cases from kidneys, bowels, and skin, though there were no gross changes in the urine. He considers the capillary circulation generally throughout the body to be at fault, and believes in stimulating in these cases, especially the cutaneous capillaries.

DR. OVERTON had seen cases of so-called malaria on Long Island, typically what would be called "biliousness" from the patient's general feelings, accompanied by subnormal temperatures. These, in well-drained localities, are not malarial but represent generally depressed physical conditions.

DR. DWIGHT L. HUBBARD of New York read a paper on

DENTAL PATHOLOGY AND ITS RELATIONSHIP TO GENERAL HEALTH.

Under the term dental pathology he would include oral pathology. He pointed out the significance of pathological conditions in the mouth for the digestive tract and for the auditory and olfactory tracts. He called attention especially, since it is neglected too much in our day, to the importance of reflexes from the mouth, and particularly from carious teeth. For the eye, he showed, by citation of cases from literature, that these dental reflexes are especially important, amaurosis and even glaucoma developing at times as a consequence of dental irritation, the latter, as Power has shown, because of reflexes from the fifth nerve setting up increased intra-ocular tension. Power insists that in all obscure eye lesions the teeth should be carefully examined.

Papers on "Urethral Stricture," by J. W. S. Gouley of New York, and on "A Convalescent's Shoe for Club-foot Cases," by Dr. S. E. Milliken of Texas, were read by title.

AFTERNOON SESSION.

DR. FLORENCE O'DONOHUE of Onondaga County read a paper on

STATE EXAMINATIONS OF MILK FOR TUBERCULOSIS.

New York State was the first to establish an inspection of dairies and of herds of cattle in order to limit the spread of tuberculosis and prevent the distribution of milk in which tubercle bacilli existed. She had been imitated in this by other States, notably by Massachusetts, that had now a very practical system of inspection, and required a certificate of health for all cattle entering the State. Unfortunately the work of inspection and especially of eradication of tuberculous cattle could not go on in New York during the last two years for lack of an appropriation for that purpose. Increasing experience has shown that much less tuberculosis comes through inhalation than was formerly thought. Especially in children is this true and as milk forms the exclusive article of diet of artificially-fed children, their danger can be readily realized. There are undoubtedly in the Hudson River counties, especially those close to New York City, tuberculous cattle. The danger of infection is constantly present. Dr. O'Donohue asked the members of the State Medical Association to interest themselves in this important question in order that the Legislature might be induced to appropriate money for the continuance of the hygienic work in the matter of eradication of tuberculous cattle that had been of such important service and had reflected so much honor on the State.

DR. MARCY of Massachusetts, in the discussion, said that in Massachusetts a great deal has been accomplished by the education of public opinion in the matter, so that now one of the first questions of the milk consumers is "Have your cows been tested for tuberculosis? Is your dairy regularly inspected?" etc. This education of public opinion in the matter he thinks extremely important.

DR. KNOPF of New York considers the time when the main source of infection in tuberculosis will be thought to be by inhalation is passing away. Not alone children but adults are infected by ingestion. Even when the initial lesion is pulmonary, the bacillus has been carried from the digestive tract in the lymph-paths and has settled in the apices of the lungs as *loci minoris resistentiæ*.

DR. O'DONOHUE, in closing the discussion, thought that the rôle of inhalation as an etiological factor of tuberculosis has been exaggerated. One proof of it is that despite the almost universality of the bacillus infections are after all infrequent, and second that the bacillus even in a favorable culture-medium is killed by six-hours' exposure to the sun, so that the much-feared danger from dried sputa getting into the air is exaggerated.

DR. DELANCEY ROCHESTER of Erie County read a paper on

THE TREATMENT OF CASES OF PULMONARY TUBERCULOSIS THAT CANNOT GO AWAY FROM HOME.

His method as illustrated by histories from his case-book consists in fresh air—the open-air treatment, with gentle exercise and hydrotherapy besides the usual drugs. He has his patients live almost entirely in the open air, take a tepid or cold douche every morning, with a brisk rubbing; a warm bath twice a week. He uses an emulsion, guaiacol and terebene in milk of magnesia, with excellent results, and uses inhalations from "the agar-holder inhaler" of the essential oils, especially oil of pepperment. Sunlight and air are, however, the curative agents for consumption, and they are of much more importance in its treatment than even any supposed effect of climate.

Dr. S. A. Knopf of New York, in discussing the paper, said that the ideal treatment of tuberculosis is not now the climatic one, but the treatment of patients in sanatoria. German experience has shown in recent years that this gives excellent results. The objection against it is its expense, but this is unfounded. At present patients in our public hospitals cost $1.16 per day, while there are sanatoria in the Adirondacks where the expense per patient per day is less than $1. It is possible then to treat even poor patients in sanatoria, thus removing so many foci of infection from among ordinary hospital patients and securing a large percentage of recoveries. The present percentage of recoveries from tuberculosis in public hospitals is practically *nil.*

In discussing the treatment of certain distressing symptoms of pulmonary tuberculosis he insisted upon the discipline of cough. In German sanatoria during meals no one is allowed to cough and a cough is scarcely ever heard. For pleurisy he referred to the good, old remedy of dry cups. For bad pulmonary hemorrhage tying off the limbs is wonderfully efficacious.

Closing the discussion Dr. Rochester reminded the Association that an effort is being made now to secure an appropriation from the State for the erection of a public sanatorium for needy tuberculous patients in the Adirondacks. The committee of investigation appointed last year as a consequence of an appeal from Erie County is about to report favorably, and he hoped that the members of the Association would see fit to use their influence to secure the passage of a bill calculated to be of such benefit to the community.

Dr. F. P. Hammond of New York County read a paper on

Genital Neuralgia and the Genito-Reflex Pains.

He insisted that severe genital neuralgia may develop as the result of but very slight pathological processes in the genital tract. It may often be cured, as he illustrated copiously by cases, by simple gynecological treatment. It is, however, sometimes a prodromal symptom of serious diseased conditions and as such may direct the physician to proper prophylaxis.

Dr. Didama of Onondaga County treated the Association to some characteristic memoranda from a wide practice. The paper was full of the quaintest, good natured humor, expressed in charming old-fashioned English, and containing withal, some excellent practical points in the simple treatment of disease as, for example, letting patients with bronchiectasis cough while leaning away out of bed so as to empty their tubes thoroughly without being subjected to the strain of coughing all the secretion up hill.

Dr. H. O. Marcy of Massachusetts read a paper, entitled

A Case of Fistulous Opening between the Ileum and Bladder; Operation; Cure.

The fistula was the result of ovarian abscess in a sterile married woman. Its position above the ileocecal valve was diagnosed by the character of the fecal portions found in the urine and the fact that milk injected high up into the colon did not come through the bladder. Dr. Marcy also presented 970 gall-stones removed from one patient, the largest number so far as he knows that has ever been taken out, and some of the smaller ones of this collection were lost before being counted.

Dr. Frederick Holme Wiggin presented a fibromyoma weighing twenty-one pounds, and a calcified fibroma weighing seventeen pounds. In the removal of the latter, in order to avoid threatened hemorrhage, he had tried rapid excision and had wounded the bladder very extensively. He had sutured it from within, however, and recovery had been practically uninterrupted.

Evening Session.

Dr. Seymour Oppenheimer of New York County read a paper on

Tuberculosis of the Middle Ear.

This affection occurs much oftener than is thought and is usually the result of infection from the pharynx. It may remain latent for a good while and its symptoms are sudden appearance of pus in the external auditory canal without previous or but very slight symptoms of inflammation. The absolute differential diagnosis is made by finding the bacillus of tuberculosis in the pus. This is not always easy and a number of specimens may have to be examined. In a large majority of the cases there are signs of pulmonary tuberculosis present. When there is not there will usually be found a primary tuberculous focus somewhere else in the body. Milligan claims that primary tuberculosis of the middle ear occurs not infrequently but this is not generally accepted. The ideal treatment would be the radical extirpation of the affected tissues but this is not easily accomplished and relapses are frequent. Attention to the general health, local cleansing, and perhaps the application of the quasi caustics, used for tuberculosis of the larynx, lactic acid, and the like are the best treatment.

Dr. Samuel Alexander of New York County then gave a lantern-slide exhibition relative to prostatic disease. A number of excellent photographs and microscopic sections of conditions in the prostate were shown. These served to demonstrate that the so-called post-prostatic vesical pouch in cases of prostatic disease is really a post-trigonal pouch. The band of muscular fibers connecting the ureteral inlets hypertrophies in the effort to empty the bladder despite the prostate impediment and

this gives rise to a bar across the base of the trigone behind which pouching occurs. From Dr. Alexander's specimens it is clear that the enlargement of the prostate is mainly glandular in character, the connective-tissue overgrowth in old cases being mainly the result of degeneration. They also make clear that the middle lobe is not so often the cause of the impediment to urination as has been thought. When the lateral lobes hypertrophy they also press the urethra downward, obstructing and lengthening it, and producing the long prostatic curve. The planes of tissue cleavage so to speak, *i. e.*, the connective-tissue capsules surrounding the glandular lobes of prostatic tissue, along which it is easy to shell them out of their beds in extirpation of the prostate, were prettily demonstrated in the microscopic specimens exhibited.

"Anthropological Rambles in the Orient, Especially in the Isle of Java, Profusely Illustrated by Stereopticon Views" by Dr. H. Ernest Schmid of Westchester County was next on the program. This was of special interest owing to our newly acquired interests in the Orient. The Dutch colonial system and methods of managing the natives was dwelt on. The thrifty Dutch have known how to rule the natives without friction, to respect their customs, and use their native aristocracy as under rulers, and have made the island one of the most prosperous colonies in the world. Dutch rule in Java will furnish some excellent lessons for the government of the Philippines.

SECOND DAY—MORNING SESSION.

The delegates from Connecticut, DRS. OSBORN and SWAIN of New Haven, presented a resolution from the Connecticut State Medical Society calling for a continuance of medical interest in the Senate Bill relating to vivisection in the District of Columbia, which has not been abandoned by its promoters, but is to be brought up again for consideration. Meantime the personal influence of individual members and the authority of medical societies is to be brought to bear to prevent the passage of an act that would inevitably lead to a curtailment of opportunities for the investigation of disease and remedies.

DR. WICKES WASHBURN of New York County read a paper on

TRUE AND FALSE MEDICAL AND OTHER CHARITIES.

He asserted once more his views to the effect that unorganized charity increases mendicancy, which is really a form of disease doctors owe it to themselves and their profession not to encourage. Legislation seems the best remedy for an evil that every one knows to exist. There is practically unanimity now as to the form which such legislation should take. Last year there had been some opposition on the part of the homeopaths, but that is now a thing of the past and the president of the State Homeopathic Society has expressed his willingness to work for the bill. There remains in opposition only certain private interests, but these will have to give way and may confidently be expected to yield to the evident necessity for reform in the matter during the present winter, when another determined effort is to be made to secure the passage of the bill which failed before.

In the discussion which followed DR. FINDLER of Renssellaer County said that one of the first abuses of medical charity that must be corrected is the treatment of clergymen free of charge. They can afford to pay and their failure to do so is an encouragement to others to neglect their obligations toward the medical profession.

DR. LEROY BROOKS of Chenango County said that the abuse of medical charity by people who can afford to pay has been fostered by the hospitals and dispensaries of New York City. Country patients have learned that they can come to the city and for a nominal charge for board at a hospital have medical or surgical attendance. Doctors themselves must strike at the root of the evil here in New York City.

DR. DUDLEY of New York County said that the medical attendants in hospitals here in New York have no choice in the matter. They are dependent on lay managers of hospitals and can only follow rules laid down by them, or resign their positions. It is the practitioners themselves in small towns or in the country who have taught their patients how to come to New York hospitals and get treated free of charge.

DR. HOLT of Maine said that practitioners in small towns sometimes do this rather than call in a consultant in their own town and so confess that there is something they do not know.

DR. HENRY L. SWAIN of New Haven, Conn., then read a paper on

ACUTE FRONTAL SINUSITIS.

This affection is more frequent since the grip than it used to be. It occurs in groups and in people living under cognate circumstances. Its symptoms are frontal pain and tenderness, usually unilateral, often with redness and swelling on that side of the forehead. Its treatment consists in keeping the nostrils thoroughly open so as to secure good drainage. Cocain is a useful drug for this, because it lessens the turgescence of the mucous tissue, but it must never be given to the patient himself to use. Aqueous extract of suprarenal capsule is an excellent remedy also, and this can be safely entrusted to the patient.

DR. DELANCEY ROCHESTER said that he has found antipyrin in 2- or 3-per-cent. solution, used with cocain, 4-per-cent. solution, very effective; the astringent property of the latter was increased and the duration of the effects made longer.

DR. SOLOMON SOLIS COHEN of Philadelphia read a paper on

MEDICINE WITHOUT DRUGS.

Though by no means a disbeliever in the benefits to be derived from drugs, but rather, on the contrary, an ardent advocate of their efficiency in many diseased conditions, yet he is ready to admit that there are methods of treatment apart from the administration of drugs that do good. Altitude, by its stimulating effect on the blood-making organs, is an important therapeutic agent in anemia, animals and men living at high altitudes having

been found to have more red blood-cells to the cubic millimeter than those living at or near the sea-level. For the same reason altitude has a beneficial stimulating effect on consumptives.

The resisted movements, with the saline and carbonic-acid baths, systematized by the Brothers Schott, and used with such success at Bad Nauheim, are certainly an important addition to our means of treating heart cases. Hot-air baths have a distinct place in the modern treatment of disease. Then apart from drugs, because they use Nature's means of accomplishing certain objects, must be considered the organotherapeutic preparations. Suprarenal-gland extract is of excellent service according to his personal experience in the treatment of exophthalmic goiter. It is useful whenever it is desired to increase blood-pressure. Thyroid extract stimulates all the emunctories and is especially useful to increase the flow of urine. Thymus extract has a distinct effect upon general nutrition and aids in the anabolic processes that are concerned with the building up of tissue.

All of these therapeutic methods apart from drugs exemplify the modern principle that the physician is here not to cure disease but to assist Nature in getting well.

Dr. Charles Phelps of New York read a paper on

THE TREATMENT OF FRACTURED PATELLA BY OPEN OPERATION.

Dr. Phelps has now operated himself in 105 cases, and his assistants under his direction in twelve cases more of fracture of the patella. He now thinks that he can say with assurance that the routine practice of opening up and suturing the patella is justified by its results. Under the old methods the results are uncertain, and extension of the limb is never satisfactory. By the open method bony union is practically always secured, and extension is usually as good as before fracture. As to the question of non-union because of deficient blood-supply to the patella, he has never seen it. The parts of the bone are always of a good pinkish hue when exposed, and there is even oozing from the fractured surfaces in many cases. New York surgeons have now employed the operation in some 430 cases practically without fatality, so that the operation must be considered now to have won its place in surgery.

Some surgeons consider that one cannot determine definitely whether bony union has taken place or not unless one has the post-mortem specimens in his hands, and this fortunately cannot be granted them, but the substance uniting the fragments has answered to all the ordinary tests for bone, and in a certain number of autopsy specimens that had been secured after death from other causes, bony union has been found. To still hesitate as to bony union in most cases is to be hypercritical.

Afternoon Session.

The afternoon session opened with a discussion on "Intestinal Obstruction," Dr. Parker Syms of New York County being the first speaker. He referred to the importance of the subject, the high death-rate, and the difficulty and necessity of early diagnosis. As a rule, at the beginning of a case but slight operative measures are necessary, once laparotomy had been done, while later, in a weakened patient, there may be some of the most serious problems in the realm of abdominal surgery to deal with.

Dr. E. D. Ferguson of Rensselaer County discussed "The Causes of Acute Intestinal Obstruction, with a Description of Their Mechanism." Besides the ordinary intestinal obstruction there occurs a set of cases with practically the same symptoms as obstruction that are so deceitfully like it that he feels sure that in many of the operations where no morbid cause is found after laparotomy, the real factor at work has been a toxic one setting up intestinal paresis. Three times he has been saved from operating almost at the last moment by finding grounds for the existence of lead paresis. Other toxic substances and ptomain poisoning may give rise to a similar state of affairs. This is undoubtedly the etiology of the cases that come to autopsy after seemingly a typical history of intestinal obstruction, and yet present no anatomical lesion post-mortem as a cause for it.

Dr. George D. Stewart of New York County followed with a paper on "The Causes of Chronic Intestinal Obstruction, with a Description of Their Mechanism." The causes of chronic intestinal obstruction cannot very easily be separated from those of acute obstruction and are not usually separated in the text-books. The two factors that most commonly lead to chronic obstruction are stricture and paresis of the intestine. Non-malignant stricture is due to cicatrization after the healing of an ulcer. Dysenteric ulcers are the most common cause. Any ulcer that has spread around the gut rather than longitudinally may be the cause. Though typhoid ulcers are often mentioned as etiological factors in the production of stricture it is doubtful if there is a single substantiated case of such a condition. Paresis of the intestine may develop as the result of impaction of feces or of nervous lesions, organic or functional, as in hysteria. Both these causes, accumulation of feces and nervous disturbance, may mutually interact to produce the paretic condition of the intestinal walls. Intestinal paresis may also be due to chronic catarrh or even to heredity.

Dr. J. D. Rushmore of Kings County then read a paper on "The Diagnosis and Indications for Treatment of Acute Intestinal Obstruction." No single symptom or set of symptoms is pathognomonic. Any of the symptoms ordinarily present and considered characteristic may be absent under certain circumstances. It is impossible by the usual methods to make an absolutely assured and early diagnosis in individual cases. Early diagnosis is extremely important. It is evident then that exploratory laparotomy at an early stage is justifiable. Practically no harm is done, and the patient is given the best show for his life. At present the mortality is high, between 70 and 90 per cent. Medical treatment is worse than useless, and delay dangerous. Our new set of statistics in the affection should be gathered from a series of cases, not with the surgeon called in on the third day, but in charge of the case from the very beginning and ready to investigate the source of the trouble as soon as its serious character is manifest. He feels sure that under such cir-

cumstances the mortality would be 20 per cent. or under and a new surgical triumph recorded.

DR. LEROY BROOKS of Chenango County followed with a paper on "The Diagnosis and Indications for Treatment of Chronic Intestinal Obstruction." These do not differ much from those of the acute variety. Exploratory laparotomy would seem to be the hopeful outlook in the matter. The surgeon must be ready to follow up his diagnosis of obstruction by immediate operation. Sometimes it must be remembered that in chronic obstruction the distention of the gut by impacted feces above the obstacle may have given rise to rupture of the coats of the intestine or to ulcerative conditions which may rupture into the peritoneal cavity. He has seen stercoral ulcers in the cecum give rise to perforative peritonitis in this way, when the seat of obstruction was farther on in the transverse or descending colon.

DR. GOULEY of New York County then read a paper, entitled "Intestinal Obstruction Due to Impaction of Feces, Gall-stones, Foreign Bodies, etc." He recalled some of the varied articles which had found their way into, and in many cases through, the intestinal canal.

DR. JOHN F. ERDMANN of New York County followed with a paper on "Intestinal Obstruction Due to Intussusception and Volvulus."

(To be continued.)

REVIEWS.

A LABORATORY TEXT-BOOK OF PATHOLOGY FOR THE USE OF STUDENTS AND PRACTITIONERS OF MEDICINE. By HORACE J. WHITACRE, B.S., M.D., Demonstrator of Pathology in the Medical College of Ohio (University of Cincinnati). Philadelphia: P. Blakiston's Son, & Co., 1897.

THIS book is designed for use by medical students during laboratory courses in pathology and as an aid for the correct interpretation and study of the sections which are given to the students in our medical colleges. The work is divided into chapters, dealing successively with inflammation, infectious granulomata, degenerations, tumors, the liver, respiratory system, thyroid gland, spleen, gastro-intestinal canal, heart, arteries, kidney, organs of generation, and the blood.

Some of the sections show much care and study in their preparation, others are too meager, and in consequence the text of the book is not even. The work contains more than one hundred illustrations, the greater number being reproductions from photomicrographs, in order to demonstrate to the student "the *actual* picture that is given by the specimen under his microscope." We are sorry to say that the author's good intentions in this matter are sadly disappointing and in most instances it is barely possible even to diagnose the organ under consideration, to say nothing of the pathologic changes. Even the roughest drawing is far preferable to a mediocre photomicrograph.

With this exception the book contains much that will be of assistance to the student and will serve as a valuable aid in laboratory work.

THERAPEUTIC HINTS.

For Trachoma, as well as for catarrhal conjunctivitis with or without implication of the cornea, EBERSON uses a 50 per cent. watery solution of ichthyol, to which a little glycerin is added. He finds that the ichthyol is much better borne than other local applications, and that it serves to effect a more speedy cure.

A Palatable Emulsion of Bromoform.—

℞	Bromoformi	ʒ i
	Tinct. tolutanæ	ʒ ii
	Syr. tolutani	℥ i
	Mucil. acaciæ	ʒ iv
	Aq. menth. viridis q. s. ad.	℥ iv.

Mix the bromoform with the tincture of tolu, and add gradually to a mixture of the syrup and the mucilage. Shake well and dilute with the spearmint water.—*Scoville.*

For Dysmenorrhea.—

℞	Ext. conii alc.	gr. xv
	Ext. scammonii alc. } aa	gr. v.
	Ext. opii }	

M. Ft. pil. No. X. Sig. One pill three times a day.—*Garrigues.*

Stimulating Expectorant in Bronchopneumonia.—

℞	Ammonii carbonat.	gr. xxiv
	Syr. tolutani	ʒ vi
	Spts. vini gallici	ʒ iii
	Syr. senegæ	ʒ iiiss
	Syr. acaciæ q. s. ad.	℥ iii.

M. Sig. One teaspoonful every two hours for a child two or three years of age.—*Goodhart and Starr.*

Liniment for Counter Irritation in Chest Affections.—

℞	Aceti cantharidis	ʒ ii
	Spts. camphoræ	℥ iii.

M. Ft. linimentum. Sig. Apply to chest at night.—*Guyon.*

For Senile Pruritus.—In addition to careful attention to the general health and the avoidance of coffee and alcoholic beverages the use of the following ointment is said to afford relief:

℞	Resorcin	gr. xv
	Ichthyol	ʒ ss
	Lanolin	℥ i.

M. Ft. ungt. Sig. For external application.

For Acute Non-diphtheritic Tonsillar Affections.—Salol is highly recommended by *de la Carrière* for its action in these cases. The pain and dysphagia are greatly relieved, the duration of the malady is lessened, and abscess formation prevented. Digestion is not disturbed so that the drug may be taken with meals. Sixty grains a day may be given to an adult, but the use of the drug must be suspended if the urine becomes dark. He prescribes as follows:

℞	Salol	gr. xxx
	Ol. amygdalæ dulc.	ʒ i
	Syr. simplicis } aa	℥ iii.
	Aq. dest. }	

M. Sig. Take in divided doses within twenty-four hours.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIII. NEW YORK, SATURDAY, NOVEMBER 5, 1898. NO. 19.

ORIGINAL ARTICLES.

THE MODERN SMALL-ARM PROJECTILE AND THE WOUND IT INFLICTS; A REPORT OF FIFTY CASES.[1]

BY WILLIAM FRANCIS CAMPBELL, M.D.,
OF BROOKLYN, N. Y.:
DEMONSTRATOR OF ANATOMY IN THE LONG ISLAND COLLEGE HOSPITAL; ASSISTANT-SURGEON TO THE KINGS COUNTY AND LONG ISLAND COLLEGE HOSPITALS; ADJUNCT-SURGEON TO POLHEMUS CLINIC.

THE evolution of the modern small-arm and its projectile marks an epoch in the history of ballistics. The changes wrought have been so radical and complete that armies have revised their tactics to meet the new conditions. Fifty years ago the old lead bullet was effective at two hundred yards. The modern rifle will fire forty shots per minute, and kill a man or a horse at two-and-one-quarter miles' range. It will be readily seen that with the advent of so powerful a weapon, with projectile modified in weight, diameter, and velocity, there must arise a difference in the injury produced and in the treatment indicated. With the progress of these engines of destruction the progress of surgery has mercifully kept pace. In the treatment of gunshot wounds to-day the surgeon achieves his most brilliant successes. In pre-antiseptic days septicemia and hospital gangrene were the shadows that hung about the cot of every wounded soldier.

Antiseptic methods and the use of the modern small-caliber bullet has radically changed the treatment of gunshot wounds, and renders possible the saving of lives and limbs as well as the restoration of useful function in a large proportion of cases. The study of gunshot wounds has received the attention of our ablest surgeons. During the War of the Rebellion the recorded results in the light of present knowledge only showed the limitations and imperfections of our art. With the discovery of Lister and the perfection of the small-arm, their study has received a new impetus and surgical practice, radical modifications.

Experimental research upon the cadaver has been carried on exhaustively. The results in actual warfare have been carefully studied during the British wars in India, the Græco-Turkish war, and of late during our own experience at Santiago. The results of many of the elaborate experiments of Delorme and Chavasse, Von Coler and Bruns have been verified in actual warfare, while Longmore and Stevenson, La Garde, and Senn have made invaluable contributions to the surgical literature of this subject. The purpose of the modern small-arm is to render as many men as possible *hors de combat* in the shortest space of time. It is not intended to mutilate tissue or even to destroy life. It is to accomplish the purpose in as humane a manner as is compatible with its mission. Its intent primarily is not to destroy the soldier, but to destroy the soldier's fighting capacity. How well the modern rifle accomplishes this purpose may be seen as we study some of the wounds which it inflicts. For "whatever increases in a marked degree the velocity of movement, force, and range of projectiles, whether it be alterations in the projectiles themselves or in the firearms from which they are discharged, changes proportionately the features of the injuries inflicted by them, and within certain limits the treatment necessary for their cure."

General Characteristics of the Modern Small-arm and Its Projectile.—In describing the modern small-arm it will be unnecessary to describe any particular make. Whether it be the Mannlicher of Austria, the Mauser of Spain, the Lee-Metford of England, or the Krag-Jörgensen of the United States, while differing in certain details they possess in common fundamental characteristics, *viz.*: they are rapid fire, of small rifled bore, and of extremely long range. The bullet averages about thirty caliber. It is composed of a core of lead, over which is a steel jacket with a thin covering of nickel to take the rifling. The gun can discharge forty shots per minute, with a muzzle velocity of 2000 feet per second, and an effective range of 4000 yards. The path which the bullet takes from the time it leaves the gun to its first point of impact is its trajectory, and this line has two motions, a motion forward and a motion of rotation.

Experiments upon the cadaver and the experience of actual warfare have shown that the severity of the bullet injury differs with the range at which the bullet strikes. In general, the severity of the injury decreases with the range. Authorities agree that in the trajectory of the bullet we may recognize at least three zones, the bullet injury differing in each zone. It is impossible to accurately define these zones. The lines of demarcation are imaginary.

[1] Read before the Brooklyn Surgical Society, October 6, 1898.

The bullet injuries are strikingly characteristic. The first division is known as the explosive zone. The bullet upon impact is said to have an explosive action, and causes terrific destruction to tissue. Bruns, whose investigations in this field have been most thorough, limits the explosive zone to 350 yards. To get a fair idea of the damage wrought in this zone, we may refer to the experiment of Von Coler, who thus describes the effect upon a full skull fired at from fifty-four yards: "The skull was completely shattered; the bones and scalp were torn into the smallest atoms, and scattered in all directions. The entire base of the skull was broken up into separate pieces of bone, the lines of fracture of which only partially corresponded to the natural sutures. There was nothing left of the brain but a pulpy substance mixed with fragments of bone, in which some individual convolutions of the brain could still be recognized."

The cause of this explosive action suggests an interesting query. Of the various explanations offered it will be sufficient to mention three. Lydston offers an ingenious solution in his analogy to the theory of the spinning top. At first the top not only rotates upon its axis but at the same time revolves about a point. It then settles down to a steady spin upon a fixed point, and finally begins to wabble as it loses its impetus. While in the steady spin upon a fixed point and the final wabbling we may see the analogy to the action of the bullet in its middle and ultimate zones, it is highly improbable that its explosive effect is due to the dual motions of rotation and revolution. The bullet receiving its impulse from behind can have but two motions—one of rotation, the other of translation. The top receiving its impulse from the side takes on for a moment the additional motion of revolution about a point.

The theory of hydraulic pressure has many eminent adherents. It is found that when a projectile is fired at a tin vessel sealed, that in addition to the holes of entrance and exit, there has been produced a twisted and torn condition in the sides of the vessel due to the pressure communicated to the liquid within. The tissues of the body are analogously considered as vessels composed largely of water, and the terrific destruction is due to the increase of pressure communicated by the bullet to the incompressible contents of the part struck. Von Coler has shown that these conclusions are defective, for he has demonstrated that similar destruction is caused by a bullet to the walls of a vessel filled with water but open at the top. Von Coler's conclusions have been verified by Stevenson, who found that it was immaterial whether the vessel were opened or closed, the destructive effects observed being the same. He therefore excludes the hydraulic theory as a scientific explanation, and offers the theory of "inherent energy" found in the high rate of velocity in the bullet at the moment of impact. He says "the soft parts themselves receive from the bullet a large amount of energy, and move outward in lines radiating from the long axis of a bullet track with such a degree of force that they act as secondary missiles on the neighboring tissues, and cause still further smashing and pulping of the tissues." The condition necessary, therefore, to produce explosive effects is great velocity in the bullet, and great resistance in the parts traversed by it. As before stated, the explosive range is about 350 yards. From this point the bullet traverses the middle zone and makes a clean-cut track until it loses much of its velocity and enters the ultimate zone where it may tilt or wabble and thus cause extensive laceration of tissue.

A matter of paramount interest to the surgeon is whether the projectile is purified by the act of firing. Longmore, after a full discussion sums up by saying: "Practical experience, indeed, contradicts the notion of the surfaces of a wound being scorched by heat whether the projectile has completely traversed the tissues concerned, or in its passage has been arrested in the flesh or by the opposition of a bone." Delorme also opposes the view that bullets can acquire such an amount of heat as would affect the tissues through which they pass or in which they lodge.

La Garde has shown that a bullet which is septic when fired will produce sepsis in the tissues which it traverses. He placed micro-organisms of anthrax on bullets and then fired them at susceptible animals. In every instance the animal succumbed, showing conclusively that there is no power of sterilization in the energized bullet. While the old lead bullet gathered its septic properties from the clothing which it carried into the wound track with it, the modern small-jacketed bullet seldom carries with it into the tissues shreds of clothing or infected substances. La Garde's experiments with powder demonstrate that while the old black powder was frequently the source of wound infection, the modern smokeless powder contains a substance which inhibits the growth of certain bacteria.

The Wounds Caused by the Modern Small-arm Projectile.—The three most striking features of these wounds are: (1) they are punctured wounds, not lacerated. This is explained by the small caliber of the projectile and its steel covering. (2) They are, as a rule, clean wounds, because of the infrequency of foreign bodies or infected material being carried along the track by the modern bullet. There being little devitalizing of tissue in the bullet track, and

the track being clean, there naturally follows the third feature, *viz.*, they heal rapidly. These characteristics are in strong contrast to the conditions imposed by the old lead bullet. The track through the soft parts was always much lacerated and contused, its diameter greater than that of the bullet. The tissues along the track were devitalized to a considerable extent. Shreds of clothing and other infected material were generally found within the track. The wounds always suppurated.

Let us examine in detail the wound inflicted by the modern small-arm bullet. The wound of entrance is circular with a hunched-out appearance, corresponding to the diameter of the projectile. The tissues of the bullet track are clean cut. The exit wound is a little larger than that of entrance (depending upon the velocity and the power of resistance of the tissues through which it has passed). It may be round, slit, T-shaped, or semicircular. The existence of a bone lesion may be diagnosed by the size of the exit wound. Von Coler, Delorme, and La Garde have shown that an exit wound, the diameter of an inch or more, is indicative of a comminuted fracture. In considering the effects of the bullet upon bone tissue we may safely postulate this rule: "The greater the resistance the greater the destructive effects produced by the passage of a bullet through animal tissue."

A great divergence of opinion exists among surgeons as to the amount of destruction caused by the modern projectile in the long bones. Referring to the rule that the destructive effects depend upon the resistance, we would expect greater destruction in compact bony tissue, less in cancellated tissue. The shafts must suffer most, the epiphyses less. The difference in effect is well illustrated in Cases XXX. and XXXVI. Both men received their wounds on the same firing-line. In Case XXXVI., the man was shot through the middle third of the femur. The bone was badly splintered, and longitudinal fissures extended for some distance along the bone. A subsequent amputation was necessary. In Case XXX., the man was shot through the condyles of the femur. A later operation to recover the bullet revealed a clean-cut tunnel through the bone about the size of a lead-pencil. The neighboring joint was not involved.

It would be fair to say that the splintering of bone decreases as the range increases, although Von Coler found that simple bullet-holes through compact bony tissue were never found even at extreme ranges. Primary hemorrhage as a cause of death on the battle-field is undoubtedly more common since the introduction of the modern small jacketed bullet.

The old lead bullet crushed and lacerated vessels. Instances of extensive injuries are reported with little hemorrhage. The new bullet makes a clean cut in the vessel, and speedy death must ensue unless the nearest comrade can render instant and intelligent assistance. An instance was recited to the writer in which a captain was shot through the thigh, severing the femoral artery. A private, standing near, went to his assistance, and by the captain's direction compressed the artery for half an hour until the surgeon arrived. A few hours later the same private received a penetrating wound of the chest (*vide* Case VII.).

It has been an interesting query to obtain from the wounded their sensations upon receiving a bullet wound. The evidence submitted shows that the mental state at the time the injury was received has much influence upon it. In the heat of excitement there were many instances where men were not aware that they had been wounded. In a few instances the men had been conscious of a wound, but kept on fighting without inconvenience. As a rule, the pain is not severe when bone is not involved. A few instances will illustrate. One man shot in the foot was carrying a number of canteens to refill at a distant stream; when the wound was received he thought he had dropped one of the canteens upon his foot. Another, shot through the fleshy part of the leg, experienced a sudden stinging pain. Another, shot through the shaft of the femur, felt as if he had been hit with a sledge. Another, shot in the ilium, felt as if his whole side had been blown out. Others shot through the chest experienced a sensation like an electric shock or sudden numbness. In most instances there is great nervous depression out of all proportion to the gravity of the injury. The impression upon a man's mind which this class of injury makes must in large measure account for the susceptibility to shock.

Whether the modern bullet will become encapsulated and remain a harmless quantity in the tissues as readily as the old lead bullet must be determined by those who have a larger field for observation at their command. The only opportunity for observing this phenomenon was in two cases in both of which the bullet was found lying in a circumscribed area of pus.

The cases to be considered are fifty in number, and came under my observation in Brooklyn. While few incontrovertible deductions can be drawn from so limited a number, yet they are full of pertinent suggestions, and as such are offered as a small contribution to the study of this class of wounds. Every man on the firing-line was provided with a "first-aid package," which contained a compress of sterilized gauze, a triangular bandage, and safety-pins. This was the primary dressing applied in each case.

WOUNDS OF THE HEAD.

CASE I.—Admitted to hospital fifteen days after injury. Bullet entered at the upper angle of the occipital bone on the left. It made its exit two inches above at the parietal eminence. The wound of exit was suppurating. There was complete paralysis of the right arm and slight paresis of the right leg. Patient left the hospital with nearly complete restoration of arm and leg function on September 7th.

CASE II.—Admitted to hospital fifteen days after injury was received. The bullet grazed the skull, causing a deep scalp wound over the left parietal region. The wound was suppurating when patient was admitted. Discharged cured.

WOUNDS OF THE NECK.

CASE III.—Admitted to the hospital fifteen days after wound was received. Bullet entered one inch posterior to angle of the mouth on the left. It split the second molar tooth and part of the alveolar process, and was deflected to the posterior pharyngeal wall, and there lodged. On admission patient suffered severe neuralgia, radiating from the occiput down to both shoulders. He was unable to make the slightest movement of his head without intense pain. There was a slight swelling on the back of the neck over the fourth and fifth cervical vertebræ. There was limited motion of the jaw, a separation of about one inch. About a week later he expectorated a quantity of pus from the wound in the posterior pharyngeal wall. August 11th, several spiculæ of bone were recovered from the pharyngeal sinus. The X-ray showed the bullet lodged alongside of the spine of the fourth and fifth vertebræ. Patient steadily improved, and was discharged August 27th with neck still stiff.

CASE IV.—Admitted to hospital fifteen days after injury was received. Bullet entered at outer margin of right trapezius muscle, two and one-half inches below mastoid process. Exit on left side of face, opposite second molar tooth. Wound healed *per primam*. There was a noticeable change in the voice sound. Voice steadily improved until time of discharge, September 7th.

CASE V.—Admitted to hospital fifteen days after being wounded. Bullet entered the under surface of the symphysis menti, and made its exit one inch to the right of the symphysis. Wound was suppurating. During convalescence patient suffered from neuralgia of the inferior dental nerve. Discharged cured.

WOUNDS OF THE CHEST.

CASE VI.—This is reported by Dr. Senn in the *Medical Record* of July 30th, as follows: "Edward O'Flaherty, Company C, 16th Infantry. Was wounded July 2d by a ball, forty-five caliber, from a bursting shrapnell. The projectile entered below the angle of the right scapula. Passed through the lung, diaphragm, liver, and lodged beneath the skin in front, between the seventh and eighth ribs. Bloody expectoration for some time, and slight elevation of temperature. July 12th, temperature normal. July 21st, patient suffers but little inconvenience from his wounds. No peritoneal or pleural effusion. General condition promises an early and complete recovery." Admitted to hospital July 27th. Wound was entirely healed. No pulmonary symptoms. Discharged cured.

CASE VII.—This case is reported by Dr. Senn in the *Medical Record*, July 30th, as follows: "John B. Senica, Company G, 22d Infantry, was wounded July 21st, by a bullet which entered his back just below the angle of the left scapula, passed upward through the lung, neck, and jaw, and emerged through the alveolar process of the right bicuspid tooth, cutting the tongue slightly. All the wounds healed in a short time by primary intention. Hemmoptysis profuse immediately after he was shot, and slight for the following few days. Left arm at first nearly powerless, with desquamation of the skin of the hand. Function of the arm returning gradually. In three weeks the patient was able to sit up for a short time each day. Physical examination of the chest at this time revealed nothing abnormal."

Admitted to hospital July 27th. Wounds were entirely healed. Physical examination showed complete flatness over the left side at the base; there was some dyspnea. Temperature ranged from 100° to 102° F. August 2d, thoracocentesis performed. Result *nil*. Patient continued to grow worse. August 23d, operation—two inches of the seventh rib was removed, and about eight ounces of pus and a large quantity of disintegrated tissue and clot removed. Patient has steadily improved. There is still loss of power in the left arm. Little improvement can be noted.

CASE VIII.—This case is reported by Dr. Senn in the *Medical Record* of July 30th, as follows: "William A. Cooper, Company A, Twelfth Cavalry, was wounded July 1st. The bullet entered an inch below the left nipple and escaped from the body an inch below the costal arch in the mammary line. It is questionable whether the bullet opened either the pleural or peritoneal cavity as the injury was not followed by any symptoms referable to visceral wounds in either the chest or abdomen, although the course of the bullet was such as to give rise to the suspicion that either or both of these cavities might have been invaded." Admitted to hospital July 27th. It was found that the ball had also entered the thigh at its middle third on the inner surface and lodged in the lower third on the outer surface. It could be felt beneath the skin in the position described. July 27th, bullet was removed. Patient made a rapid recovery. It is believed that the bullet did enter the lung as a history from the patient elicited the fact that he did suffer from some dyspnea immediately after being wounded and expectorated some blood.

CASE IX.—This case was reported by Dr. Senn in the *Medical Record* of July 30th, as follows: "Henry Mitchell, Company C, Seventh Infantry was wounded July 1st. The bullet entered over the right acromion process, passed through the apices of both lungs, and escaped through the second inter-

costal space above the right nipple. No hemoptysis at any time; dry cough, and a moderate hemothorax on the right side. Has suffered from quotidian form of malarial fever which is yielding to quinin. A speedy and complete recovery is expected." Admitted to Long Island College Hospital July 27th. Wounds were healed. No pulmonary symptoms. Patient has had some elevation of temperature which readily yielded to quinin, and was subsequently discharged cured.

CASE X.—Admitted to hospital twenty-three days after injury was received. Bullet entered the flexor surface of the left forearm and emerged through the skin and entered the outer surface of the arm and escaped at the inner surface. Entered the chest below the axilla, and lodged beneath the eighth rib near its vertebral attachment. In its course it produced a compound comminuted fracture of the humerus at the middle third; a penetrating wound of the lung and a fracture of the eighth rib at its angle. On admission temperature ranged from 100° to 103° F. There was marked dyspnea, a dry cough, and dulness over the left chest. The bullet could be felt beneath the fragments of the rib. Patient's pulmonary symptoms grew worse. July 19th, thoracocentesis performed. One pint of serosanguineous fluid was removed. July 22d, bullet without its jacket was removed, and two pints of purulent fluid and necrotic tissue were removed. After operation patient improved, but a large quantity of pus and débris was discharged, and it was decided to enlarge the opening for freer drainage. August 10th, part of one rib was removed, and a large quantity of necrotic tissue and disintegrated clot curetted away. The jacket of the bullet was recovered at this time. Patient is steadily improving.

CASE XI.—Admitted to hospital fifteen days after being wounded. Bullet entered on left side of neck one-half inch from the median line opposite thyroid cartilage. Exit on right side of chest at the fifth rib opposite the posterior axillary line. It fractured the clavicle at the inner third, injuring the second part of the subclavian artery and producing an aneurism which afterward proved to be arteriovenous in character. The fragments of clavicle were separated about one-half inch, beneath which could be felt a pulsating tumor giving a distinct bruit. Wounds healed *per primam*. No pulmonary symptoms present.

CASE XII.—Admitted to hospital fifteen days after the wound was received. Bullet entered second interspace one inch to right of sternum and made its exit just below spine of scapula. Patient suffered some from dyspnea and hemoptosis. Wounds healed *per primam*. Patient made a complete recovery.

CASE XIII.—Admitted to hospital fifteen days after being wounded. Bullet entered the second interspace to the right of sternum and made its exit just below the spine of the scapula on the same side. Wounds healed *per primam*. No further symptoms.

CASE XIV.—Admitted to hospital twenty-five days after injury was received. Bullet entered on left side at about the fifth rib in the axillary line and emerged on the right between the seventh and eighth rib to the outer side of mammary line. Both wounds of entrance and exit healed. Two days before admission patient fell and struck the wound of exit over the edge of a bath-tub. There resulted a swelling and subsequent rupture leaving a fistula discharging bile and mucus. Patient a few days later removed to hospital on Governor's Island.

CASE XV.—Admitted to hospital fifteen days after wound was received. Inspection showed a wound of entrance on the left side at the eighth rib in the posterior axillary line. No wound of exit. Patient complained of pain in the hip-joint, and there was anesthesia of the right lower extremity. The X-ray gave no result. August 27th, patient still complained of pain and the anesthesia had not subsided when discharged.

CASE XVI.—Admitted to hospital fifteen days after wound was received. Inspection showed a wound of entrance at the sixth interspace behind the axillary line and a wound of exit in the corresponding space on the opposite side. Patient suffered some from dyspnea and hemoptysis. July 20th, discharged with slight cough and dyspnea.

Out of the eleven cases of penetrating wounds of the lung, only two were infected, leaving eighty-two per cent. clean wounds. The symptoms in the non-infected cases were slight dyspnea and hemoptysis which passed away in a few days. In the two infected cases the symptoms were of slow onset and culminated in operation at the end of four and seven weeks, respectively.

WOUNDS OF THE EXTREMITIES.

CASE XVII.—Admitted to hospital twenty-five days after injury was received. Bullet entered outer side of arm three inches below the acromion and was removed at the field hospital from the left side of the neck at the outer edge of the sternomastoid muscle. Exit wound was suppurating.

CASE XVIII.—Admitted to hospital fifteen days after being wounded. Bullet entered one and a half inches below apex of shoulder. No wound of exit. Wound healed *per primam*. X-ray gave no results.

CASE XIX.—Admitted to hospital twenty-five days after being wounded. Bullet entered two and a half inches below the acromion on the outer surface of the right arm and lodged. Wound was clean. The X-ray showed the bullet lodged just below the clavicle at the middle third. Presence of the bullet gave no symptom and was left *in situ*.

CASE XX.—Admitted to hospital fifteen days after being wounded. Bullet grazed the olecranon process leaving a granulating wound of about two and a half inches. Patient said that small portions of olecranon were removed at the field hospital.

CASE XXI.—Admitted to hospital fifteen days after being wounded. Inspection showed a bullet wound of entrance at the fold of the elbow and a wound of exit on the inner side about one and a half inches above the condyle. The bullet severed the brachial artery. It was ligated at its middle third at the field hospital. On admission, wound of exit

was healed. Wound of entrance suppurated. Six days after admission an incision was made over the flexor surface of the forearm from the elbow to the wrist. The sloughing flexor muscles and tendons were cut away. The arm healed, but the hand has little function.

Case XXII.—Admitted to hospital fifteen days after being wounded. Bullet passed through the fleshy part of the forearm. Wound of exit was found suppurating.

Case XXIII.—Admitted to hospital fifteen days after being wounded. Bullet passed through the fleshy part of the right hand. Wound was suppurating. There was complete recovery of hand function.

Case XXIV.—Admitted to hospital fifteen days after wound was received. Inspection showed a bullet wound of the hand causing a compound fracture of the third metacarpal bone. Wounds were suppurating. Patient recovered with a stiff finger.

Case XXV.—Admitted to hospital fifteen days after being wounded. Bullet entered two inches below the crest of the ilium on the right side and was found by the X-ray lodged on the inner side of the thigh at the middle third over the femoral line. Bullet could not be found at operation. Patient made a complete recovery.

Case XXVI.—Admitted to hospital fifteen days after being wounded. Bullet entered one inch below the crest of the ilium on the right side, and came out of the buttock just above the anal cleft. It re-entered the left buttock and made its exit just above the gluteal fold. Wounds of exit suppurating.

Case XXVII.—Admitted to hospital fifteen days after being wounded. Bullet entered one inch below the anterior superior spinous process on the left and made its exit through the left buttock. Wound of exit suppurating. Patient complained of neuralgic pains in front of thigh and leg. Pain subsiding at time of discharge.

Case XXVIII.—Admitted to hospital fifteen days after being wounded. Inspection showed that the bullet had passed through condylar extremity of the femur. Entered the upper portion of the calf of leg and made its exit three inches below. The wound suggests the posture of the soldier when injured. There was no joint injury. Some suppuration from the wound of calf. Recovery complete.

Case XXIX.—Admitted to hospital twenty-five days after being wounded. Bullet entered the outer surface of the thigh at the middle third and lodged. On admission there was found a fracture of the femur at the middle third and a suppurating sinus leading down to the seat of fracture. July 28th, the opening was enlarged and several fragments of bone, together with the bullet removed. Patient is convalescing and the union is firm.

Case XXX.—Admitted to hospital twenty-two days after being wounded. Bullet entered the thigh at the lower third. Passed through the femur and lodged behind the internal tuberosity of tibia as shown by the X-ray. At operation the bullet was recovered and there was a hole tunneled through the femur about the diameter of a pencil. Patient made an excellent recovery.

Case XXXI.—Admitted to hospital twenty-five days after being wounded. Bullet entered three inches below the crest of ilium on the left and outer surface of thigh, and came out just below Poupart's ligament on the inner surface. It passed over and injured the foreskin, making a circumcision necessary. Exit wound suppurating.

Case XXXII.—Admitted to hospital twenty-three days after being wounded. Bullet entered the soft tissues of thigh two inches above the condyle of the femur. Bullet was found by the X-ray lodged in the tissues two and one-half inches above the external condyle. The bullet was removed and a circumscribed area of pus found surrounding it.

Case XXXIII.—Admitted twenty-five days after being wounded. Bullet entered the upper third of the right thigh on the outer side, and came out at the lower half of the thigh on the inner side. Wound of exit suppurating.

Case XXXIV.—Admitted to hospital fifteen days after being wounded. Inspection showed a bullet wound in the fleshy part of the right thigh. Wound healed *per primam.*

Case XXXV.—Admitted to hospital fifteen days after wound was received. Bullet wound of the soft parts of thigh at the middle third. Exit wound was suppurating.

Case XXXVI.—Admitted to hospital twenty-three days after being wounded. There was a bullet wound of entrance on the outer surface of the thigh at the middle third. No wound of exit. There was a fracture of the femur and a sinus leading down to the bone ends, from which exuded large quanties of pus. August 2d, an incision was made over the sinus track, and a number of small fragments of bone and a flattened piece of lead removed. Thorough drainage was established and the limb immobilized. August 9th, the patient showed signs of general septic invasion, and amputation of the thigh at the middle third was performed. Patient is making an excellent recovery. The Mauser bullet was found in the amputated limb just behind the head of the tibia in a half an ounce of pus. Its shape was fairly well preserved. The bone was badly comminuted, and there were a number of longitudinal fissures.

Case XXXVII.—Admitted to hospital twenty-five days after being wounded. Bullet passed through the fleshy part of thigh just above the knee. Wounds healed *per primam.*

Case XXXVIII.—Admitted to hospital fifteen days after being wounded. Bullet passed through the soft tissues just above the knee. Wound healed *per primam.*

Case XXXIX.—Admitted to hospital fifteen days after being wounded. There was a bullet wound of the fleshy part of the leg near the ankle. The entrance wound had healed *per primam*, leaving a small area of granulating surface at the exit wound.

Case XL.—Admitted to hospital fifteen days after being wounded. Bullet entered at the lower

angle of popliteal space, and passed obliquely downward four inches, emerging at the inner side of calf. Wound healed *per primam*.

CASE LXI.—Admitted to hospital twenty-two days after being wounded. Bullet passed through the lower third of tibia, producing a compound comminuted fracture. July 28th, wound was enlarged, fragments of bone removed, and through-and-through drainage established. No communication with the ankle-joint. Patient has firm union, and wound is rapidly healing.

CASE XLII.—Admitted to hospital twenty-two days after being wounded. Bullet entered the leg at the middle third. Was deflected by the tibia, and came out three inches below. Wound healed by first intention.

CASE XLIII.—Admitted to hospital twenty-five days after being wounded. Bullet entered the outer side of the calf, and emerged three inches below. Exit wound was suppurating.

CASE XLIV.—Admitted to hospital twenty-five days after being wounded. The bullet glanced across the crest of the tibia of the left leg, causing a compound fracture of that bone. Wound suppurating. Patient is making a rapid recovery.

CASE XLV.—Admitted to hospital fifteen days after wound was received. Bullet wound through the soft tissues of the left leg. Wound healed by first intention.

CASE XLVI.—Admitted to hospital fifteen days after injury was received. Inspection showed a bullet wound through the fleshy part of the leg near the ankle. Healing *per primam*.

CASE XLVII.—Admitted to hospital fifteen days after being wounded. Inspection showed a bullet wound of the ankle-joint. The bullet had evidently passed through both malleoli. Wound healed *per primam*. Function of joint perfect.

CASE XLVIII.—Admitted to hospital fifteen days after injury was received. Inspection showed a bullet wound passing through the third metatarsal space and perforating the sole. Suppurating wound of exit.

CASE XLIX.—Admitted to hospital fifteen days after being wounded. Inspection showed a bullet wound of the foot in the metatarsal region. Slight suppuration at the wound of exit.

CASE L.—Admitted to hospital fifteen days after wound was received. Inspection showed a bullet wound of the foot through the second metatarsal space. Wound healed by first intention.

Of these 34 cases, 15 were clean, 19 infected. Dr. Senn believes that many wounds of the extremities were infected because of the unnecessary change of dressings due to a natural desire of the men for treatment and the indulgence of the surgeons. Of the 19 infected wounds 11 were infected at the wound of exit, due in part, perhaps, to the extensive laceration and the devitalization of tissue at this point. Five were compound fractures, 2 were infected wound tracks, the tracks being short, the infection undoubtedly an ascending one, starting from the wound of exit, and 1 was an encapsulated bullet. There is no doubt that the majority of infected wounds were the result of unnecessary handling and the disturbance of the primary dressing.

CONCLUSIONS.

From a study of the cases reported we may conclude that all wounds inflicted by the modern small-arm projectile require immediate protection from bacterial invasion by the application of suitable dressings; that the great majority of these wounds require this and nothing more. It would almost be inferred that the inventor of the modern bullet was possessed of surgical instincts, so harmoniously does it work in accord with modern surgical technic. In the mid-range at least we may say that it incises without devitalizing; it penetrates without infecting. Modern bullet wounds are clean wounds. Their treatment consists in keeping them clean.

While the damage to the shaft of the long bones must always be considerable, the ends of the long bones suffer less; joint complications are few and amputations rare. Few bullets will be found lodged in the body because of the great velocity and penetrating power of the steel-jacketed projectile. The value of the X-ray in this class of injuries is simply inestimable. The probe with all its attending disadvantages has been relegated to a minor sphere of usefulness. The sense of sight has superseded the sense of touch, and surgical practice has advanced another step toward the ideal by Roentgen's great achievement.

Since primary hemorrhage must be the cause of many deaths on the battle-field, it is imperative that every soldier in our army and National Guard should receive instruction in the location of important arteries and the ordinary means of hemostasis. In such an emergency many lives could be saved by the intelligent efforts of a comrade. We might, too, with advantage, teach the value of the first-aid dressing and its proper method of application. The maxim of Nussbaum cannot be too strongly emphasized: "The fate of a patient seriously wounded is almost entirely in the hands of the surgeon who applies the first dressing."

I wish to acknowledge my obligations to Dr. H. B. Delatour for the use of this material, in whose service the patients were treated.

Death of Mrs. Fordyce Barker.—Mrs. Barker was so intimately associated with her husband, the late Dr. Fordyce Barker of New York, not only in his social but also his professional career that it seems fitting to record in our columns the fact that she died at Norwich, Conn., October 28, 1898.

ATONY OF THE STOMACH.[1]

BY A. J. PATEK, M.D.,
OF MILWAUKEE, WIS.

ATONY of the stomach is a common affection, yet a condition which—not recognized as a distinct disease requiring definite measures for relief—gradually passes into a stage in which treatment is of little avail. Because of its practical importance, then, I wish to say some words concerning this affection, its cause, symptoms, diagnosis, and treatment, and to cite a few illustrative cases.

The name "atony," though commonly used to designate this condition is, correctly speaking, rather inaccurate, since it means "an absence of tone." This affection is, however, decidedly not of this character, and is better designated by the terms "hypotonia" (Bouveret) and "myesthenia gastrica" (Boas). Boas makes use of a classification of gastric motor disturbances that has met with favor by many; he speaks of mechanical insufficiency of the first and second degree, the first degree being so-called "atony," the second, "gastrectasia." By atony — to adopt the popular term—we mean a condition of diminished motile power of the stomach, resulting in an inability on the part of this organ to rid itself of its contents in a normal period of time. We may further speak of primary and secondary forms of atony, and this brings us to a consideration of the conditions under which it exists, and its causes.

Boas has observed primary gastric myesthenia occurring as a congenital or hereditary defect, and even finds it running in families, though Ewald doubts the frequency of primary atony, that is, a muscle hypotonicity pure and simple, and sees in this condition a strong neurotic element, leaning to its classification among the neuroses. Among the forces at play in bringing about an atony secondarily, we may state that general diseases, fevers, anemias, etc., that leave the system in an asthenic condition, often exert a similar influence upon the stomach-walls, reducing their tone likewise. Excessive eating and drinking, by the constant strain put upon the stomach-walls, may cause a dilatation and atony, though, as Pepper and Stengel[2] point out, dyspeptic symptoms are present also, and it is quite possible that the primary cause of atonic dilatation is some other gastric glandular disturbance. Atony may associate itself with any, and does associate itself with many forms of gastric disturbance, and thus it becomes a difficult matter to say which of these was the primary condition, and we find ourselves dealing with a vicious circle of circumstances. A primary gastric myesthenia soon has added to it disturbances of the gastric glandular functions, and *vice versa*, many pathological gastric conditions give rise to the complication, atony.

Indiscretions in diet, and, as already said, excessive eating, more particularly the inordinate use of liquids, such as alcohol, coffee, tea, soup, and the long-continued use of cathartic waters, etc., are the most common direct causes of this form of gastric trouble. There are also other and graver causes, such as internal and external obstructions to the expulsion of the stomach-contents, or gastric ulcer and carcinoma leading to secondary muscular changes, and these conditions frequently pass on to mechanical insufficiency of the second degree (Boas)—gastrectasia.

Among the more prominent subjective symptoms, we may briefly mention the following: a feeling of decided fulness after eating, and satiety before the full meal is taken, gastric distress of variable duration, eructations, dizziness, and constipation. The ingestion of fluids is especially prone to cause a sensation of weight. Neurasthenia, with all its pronounced and peculiar manifestations, is a condition frequently complicating long-standing atony, and with it obstinate constipation and fermentation are also troublesome complications.

The objective symptoms are of a more distinctive character, and call for an examination of the stomach with reference to its size, its power of expulsion and tonicity, and in a minor degree, the chemistry of its secretions.

Though atonic stomachs are not always dilated, this is so generally the case as to almost make it a rule. On the other hand, a large stomach is not always atonic, for it may have normal power of expulsion, a condition not frequently met with, and known as megalogastria. (Ewald.)

Normally the lower border of the stomach extends to a point about 1¼ to 2½ inches above the umbilicus, and an organ whose large curvature is found at or below the umbilicus may be considered to have abnormal dimensions, providing the condition be not one of a displaced organ—a gastroptosis.

The elicitation of the splashing sound ("*clapotement*" of the French) and the percussion of the stomach are among the important methods of physical examination. The splashing sound is elicited by a succession of quick shocks over the stomach-area with the tips of the fingers, and when present upon the taking of a small quantity of fluid, one cup, or several hours after a light meal, a myesthenic state may be inferred. An error may creep in if the contents of the colon are liquid; in such case the bowel should either be evacuated or a re-exam-

[1] Read before the Wisconsin State Medical Society.
[2] *American Journal of the Medical Sciences*, January, 1897.

ination made when the feces are of normal consistency.

Percussion, unless the stomach be artificially distended with fluid or gas, is, as a rule, quite unsatisfactory, though Pepper and Stengel (*loc. cit.*) seem to be well pleased with the results they obtained with auscultatory percussion. I have tried this method in a few cases, with fairly satisfactory results; it is surely far superior to the ordinary method of percussion.

Artificial distention is most easily brought about by administering a Seidlitz powder, drinking the two portions separately, so that the evolution of gas takes place in the stomach, or better—and fraught with less danger—by pumping air into the stomach with an ordinary bulb-syringe through a previously passed tube. Electric illumination of the stomach (gastrodiaphanoscopy) is also used, but has found few enthusiastic supporters. Dehio's method, that of having the patient drink two or three tumblerfuls of water while standing, and then determining the lower border by percussion, is quite satisfactory. The Röntgen-ray gives promise of becoming a very useful adjunct to the methods of diagnosticating the position and contour as well as abnormalities of the stomach and intestines. Boas and Levy-Dorn[1] use for this purpose large-sized celluloid-coated gelatin capsules filled with metallic bismuth. This capsule is swallowed, and since it permits but few rays to pass through, and hence throws a satisfactory shadow, can be followed in its passage from stomach to bowel until it leaves the system, and its position noted at various periods. The results thus far obtained have, according to the authors, been very encouraging.

Various tests of motor-function are made use of—the best being Leube's test-meal, consisting of a plate of soup, a piece of steak, a slice of bread, and a glass of water. Seven hours after its ingestion this must normally have passed out of the stomach. If, upon examination with the stomach-tube, solid particles are found remaining, a motor weakness may be argued.

Ewald's salol test has been found sadly deficient by many observers, but instead of examining the urine to record the time that elapses before the salol begins to be excreted, Huber has suggested a modification, testing for the length of time during which excretion takes place. He claimed that a normal condition existed if the urine reaction (purplish precipitate upon the addition of ferric-chlorid solution) disappeared after twenty-seven hours, and that a delay in the expulsion of the stomach's contents could be argued if the reaction continued many hours after. The reliability of this is adhered to by a few, but fought by many.

The chemical examination of the stomach-contents shows, in an uncomplicated case, nothing distinctive. The acidity may be subnormal, but more frequently there is a normal or hyperacid condition.

The diagnosis of gastric atony is not difficult if the various subjective, and, more especially, the objective, signs as detailed, are elicited. In the differential diagnosis gastrectasia and gastroptosis must be considered. As symptoms of gastrectasia we may mention: excessive dilatation, habitual vomiting of enormous quantities—frequently containing remains of a previous day's meal, and this in a state of much fermentation, hyperacidity, and usually sarcinæ and yeast fungi; morning lavage reveals remains of the previous evening's meal, a condition never found in atony; the general health of a gastrectatic patient is very bad, and emaciation is often quite extreme.

Gastroptosis, a sinking of the whole stomach, is usually associated with a certain degree of enteroptosis. There are frequent attacks of severe pain after meals, and marked constipation. Examination reveals the following: considerable emaciation, distention in umbilical region and relative flattening in epigastrium, succussion-splash demonstrable at some distance, splashing sound elicited over a vertical area of six inches (two above and four below umbilicus), covering the visible distention, and making it possible to definitely outline the large and small curvatures without artificial distention. In addition, there are evidences of the retention of food in the stomach for longer than normal periods. In this case we must diagnosticate dilatation in addition to dislocation of the organ.

In place of detailing the treatment prescribed for the average patient, I shall dwell on two illustrative cases of atony, one of very mild character, the other of very severe type, and the treatment of these patients may be taken as that quite generally applicable to all this class of cases:

CASE I.—E. K., aged twenty-two years; office clerk; leads a very sedentary life. Complaint of gastric distress is of three-months' standing. Acidity and fulness are experienced after eating, and there is considerable gaseous distention and constipation. There is no vomiting. Four hours after eating a light meal splashing could be elicited in the epigastrium, its lower limit being 5 cm. (1½ inches) above the umbilicus.

Auscultatory percussion of the stomach covered this area quite accurately. The patient refused to have a stomach-tube passed, so no direct examination of gastric contents could be made. However, from the data given, I felt justified in making the diagnosis: atony of mild degree, without dilatation. He

[1] *Deut. Med. Woch.*, No. 2, 1898.

was advised to take as much exercise as possible. In addition he was given a cascara laxative and told to make frequent flexion-movements of the thigh on the abdomen while lying in bed—these movements acting as a massage, strengthening the abdominal muscles. For direct tonic and stimulant action nux vomica was given in pill form, combined with soda bicarbonate. Four weeks later he reported himself well, and physical examination elicited nothing abnormal.

This, it is true, was a mild case, but the tendency of the disease is to progress, and the earlier the proper treatment is instituted the more satisfactory are the results for both physician and patient.

I wish now to detail another case of atony, but one of very different character, since it shows us the disease in a very advanced stage, bordering on gastrectasia, and illustrates the symptoms, diagnostic points, and treatment in an instructive and satisfactory manner.

CASE II.—Male, aged twenty-eight; bookkeeper by occupation; has been complaining of gastric discomfort for about ten years. His habits have been fair; alcohol and tobacco are used moderately; when careful with diet feels more comfortable, but frequently indulges in heavy and rich meals. Complaint now is of gastric uneasiness and a feeling of weight and fulness of several hours' duration after eating. Does not vomit. Fluids especially occasion distress. Several times, after midnight suppers, he has had to remove contents of stomach on the following morning by means of the stomach-tube, such was the uneasiness felt. He has come to me on several occasions, an hour or two after eating, to have his stomach washed out and relieved of its distress-giving contents.

Ordinarily no residue of the evening meal is ever found in the stomach on the following day, and this fact was thoroughly tested. Gas eructations are frequent; appetite good; there is but little epigastric pain or sensitiveness to pressure. During the past few years he has had various neurasthenic symptoms: giddiness, drowsiness, lack of energy and concentration of thought. The bowels are markedly sluggish, in fact, there has not been an unaided movement for several years. Occasionally great abdominal distention occurs several hours after eating, and this accumulation of gas causes great discomfort.

Examination reveals the presence of the splashing phenomenon four hours after a very light lunch, and after two tumblerfuls of water are taken it can be easily elicited as low as the umbilicus. I did not artificially distend the stomach but light percussion seemed to bring its lower border about one inch below the umbilicus. Upon the results of the salol test alone I should not base positive conclusions, but with other symptoms pointing to a dilatation and motor-insufficiency, I think it significant that the excretion of the salol in the urine began long after what has been considered the normal period, and continued, instead of about twenty-seven hours, more than forty hours after its ingestion. The stomach contents when removed one hour after a Boas-test breakfast, consisting of a roll and a large glass of water, showed but little undigested matter, slight fermentation; the total acidity varied at different times between 0.10 per cent. and 0.27 per cent. (normal 0.15–0.20 per cent.); free HCL. was always present, lactic acid absent. Unfortunately a Leube test-meal was not taken at this time, but I considered the other signs sufficient to warrant the diagnosis of gastric atony, without passing the tube for another examination. Abdominal massage, galvanization, and faradization, both intra- and extra-gastrically, properly regulated diet, strychnin with soda, salol, laxatives, etc., constituted the general treatment. Four months later the Leube test-meal was given and the stomach was found to have completely emptied itself in the normal period of time—seven hours. Moreover, the splashing phenomenon was practically absent; the lower border of the stomach descended but little beyond the normal, and the salol test, taken for what it is worth, exhibited a positive reaction at what is considered the normal period—sixty minutes after its ingestion, and disappeared altogether after a lapse of twenty-seven hours. The intestinal atony that also exists, still gives considerable annoyance.

As to the treatment of gastric atony the following general directions may be given: All discoverable causes, such as anemia, condition of exhaustion, etc., should be attended to and rectified as far as possible; the excessive use of alcohol and other liquids must be stopped; the diet must be properly regulated: it should consist of easily digested foods, and better than three full-sized meals per day are five meals, each of smaller quantity and taken at shorter intervals. The gastric contents should be tested occasionally, if the acidity is above normal, meat diet is more easily digested; if subnormal, a lighter diet, consisting of light meats, vegetables, etc., is indicated; liquids are to be used in small quantities; fresh fruits frequently set up fermentation, stewed fruits on the other hand, being usually well borne. A general tonic treatment is to be highly recommended; deep massage of the abdominal walls, calisthenics, hydrotherapy, electricity, both faradic and galvanic, and applied externally as well as intraventrically. Of various drugs that may be used, strychnin is the best' and with it may be combined a laxative, soda bicarbonate if necessary, salol, or salicylic acid, if there is much fermentation, etc. The constipation must be combatted with suitable diet and an occasional laxative. Drastics should be avoided. Systematic lavage of the stomach is uncalled for, since in atonic conditions no residual food is found in the stomach in the morning, and therefore, lavage accomplishes no purpose.

To summarize then, we record as subjective symp-

toms of gastric atony: Fulness, weight, and distress after eating, early satiety, eructations, nervous symptoms, and constipation. Objective signs: Atonic dilatation and deficient motor power. Treatment: Dietetic, general, and tonic.

CARBONIC-ACID GAS; ITS PHYSIOLOGICAL ACTION AND THERAPEUTIC EFFECT, AS SEEN IN EMPHYSEMA OF THE LUNGS, ANEMIA, WHOOPING-COUGH, DYSENTERY, AND IMPOTENCE.

BY A. ROSE, M.D.,
OF NEW YORK.

(Continued from page 548.)

3. *Carbonic-Acid Gas as a Therapeutic Agent in Chlorosis, Asthma, and Emphysema of the Lungs.*—The physicians of olden times were aware of the anesthetizing qualities of carbonic-acid gas. Local application of carbonic-acid gas was still a favored remedy of English physicians of the Eighteenth Century. In the year 1832 Professor Mojon of Genoa recommended carbonic-acid gas douches against dysmenorrhea, a treatment which had been known and had been forgotten again. Brown-Séquard demonstrated the anesthetizing effect of the gas on the larynx. In former times carbonic-acid gas inhalations of a specified degree were a well-known, extensively employed therapeutic measure. From the observation that the fumes of freshly plowed earth did good service to consumptives, or at least seemed to do, the conclusion was arrived at that the carbonic acid of these fumes was the essential agent. From the reports on the curative effect it can be inferred that the relief obtained was due to the narcotic action of the gas. The application of carbonic-acid gas in this form was abandoned. An unintentional admission of carbonic-acid gas by way of respiration takes place sometimes during bathing of patients in carbonic-acid baths. There are cases on record in which the gas escaping from the bath has brought on more or less severe intoxications. Ordinary precautions have to be observed. However, the direct poisonous effects of carbonic-acid gas have been exaggerated, for it has been found that air containing from fifteen to twenty per cent. of this gas can be breathed without producing any immediate evil effect, providing the quantity of oxygen in the air be increased in a like proportion. Intravenous injections of carbonic-acid gas which have been carried out repeatedly on animals are not qualified to be considered for methodical application as a therapeutic measure.

The physicians of Nauheim were the first who gave a scientific description of the influence of carbonic-acid water-baths in different nosological conditions, especially in disorders of circulation. Great praise is due to Beneke, the first who demonstrated that the water-bath saturated with carbonic-acid gas is a powerful and effective stimulant for the enfeebled heart. He was the first who had the courage to place dyspnetic patients suffering from uncompensated valvular disease into the bath. His beginning was rewarded by most significant success. He also tried the effect of the baths in other nosological conditions, in arthritis and nervous diseases. Schott and Groedl continued to work on the basis which had been laid down by Beneke, and their success is universally known. The brothers Schott have established a system of their own of physical therapeutics of disorders of circulation in which carbonic acid plays a rôle. A number of contrivances have been recommended to give artificial carbonic-acid baths as substitutes for the natural ones of Nauheim, among them those of Ewald, of Rudinger, and of Körting.

The induction of carbonic acid into the circulation by way of the rectum is an idea of recent date, at least we find in older literature only a few notes here and there according to which this form of application has been thought of. Bergeon, in the year 1886, published his new method of treatment of phthisis, based on the fact established by Claude Bernard, that volatiles introduced into the rectum will pass through the venous blood-current to the lungs where they will be eliminated without entering into the arterial system or developing any deleterious effect. Bergeon calculated by means of enemata of sulphuretted hydrogen diluted with carbonic-acid gas to destroy the tubercle bacilli within the lung tissue. In the course of events his method soon became widely known and was extensively practised in France and in America. In Germany almost no notice was taken of it. Among the eighty publications on this method collected by Wesener, only three are of German origin. The great majority of authors confirmed the observation that the general condition of the patients treated was improved, but they soon found that the tubercle bacilli did not disappear, and that not the sulphuretted hydrogen but the carbonic acid was the effective agent; whatever benefit was derived was due to the carbonic acid solely. Although some of the most distressing symptoms of phthisis were at once relieved, namely, the general condition, the cough, the expectoration, the night-sweats, the fever, and especially the dyspneic difficulties and the feeling of oppression, the method was abandoned because it did not answer the main expectation; it did not cure tuberculosis. Having thus been dis-

appointed, nobody for a while grasped the idea of making use of the undisputable healing power of the gas in other but tuberculous affections of the lungs. Physiological and pharmacological interests should have induced consideration.

The large amount of carbonic-acid gas having been induced into the rectum passes through the veins, enters into the alveoli and from there, obeying the physical law, is diffused in an upward direction, and thereby an access over the normal process of the diffusion of the gases takes place, that is, more than the normal amount of carbonic-acid gas ascends, and more than the normal amount of oxygen descends, the ventilation of the air-passages thus being increased.

Increased ventilation of the lungs brought on by increased respiratory activity, that is more profound inspirations, causes a larger amount of oxygen to be retained in the body, but only a small part of this extra amount of oxygen enters the blood; by far the greater part enters into the composition of the residual air, enriching it with oxygen. With the increased activity of the respiratory organs the body uses up a larger amount of oxygen than normally, and the small extra amount in the residual air is needed to cover the deficit, and there is not enough left to add noticeably to the oxygen of the blood. Increased ventilation of the lungs brought on by increased diffusion as a consequence of carbonic-acid inflation of the rectum is in all probability followed by increased accumulation of oxygen in the blood. This is the main factor of the curative effects which thus far have been observed.

Ephraim administered carbonic-acid gas per rectum to a number of out-door patients. He gave, as a rule, one, and only in exceptional cases two sittings a day. Liquefied gas in the manner described was employed. The patients treated were suffering from chlorosis, phthisis, and asthma. Of chlorosis he had eleven cases (girls of the age of from sixteen to twenty-two years). The circumstances surrounding them were most unfavorable in regard to health. All these patients belonged to the poorer classes; they were obliged to earn their living by working in factories. Their fare was correspondingly a very poor one. In order to secure the results of the carbonic-acid treatment pure and simple, nothing was changed in regard to occupation and mode of living of these patients while under treatment. The cases selected were all of a severe form of chlorosis, and except in one instance they all were of long standing and had been under treatment. One of these patients was not benefited by the carbonic-acid gas; in two cases there was marked improvement, and in seven complete cure. The examination of the blood was made in nine out of the eleven cases, and was confined to the number of red blood corpuscles. An unmistakable, and in most instances a considerably increased, number of red blood-corpuscles was noted. Although there was no examination made in regard to the amount of hemoglobin, Ephraim thinks that there must have been, judging from the improved general condition of the patients, an improvement in this direction. It may safely be said that Ephraim's experience shows that carbonic-acid-gas treatment is an excellent auxiliary in the treatment of chlorosis. The result of the examinations of the blood support the theory that the healing effect is due to an increased induction of oxygen into the blood. For asthma he treated 20 patients, 10 of whom were suffering from true bronchial asthma, 5 from neurasthenic asthma, 3 from emphysema of the lungs associated with bronchitis and asthmatic attacks, the nature of which could not be exactly defined. All the ten patients suffering from bronchial asthma were relieved from these difficulties for shorter or longer periods of time. This result was a surprise, considering that the affection is, as a rule, unyielding to all sorts of treatment. In these cases the effect of the carbonic-acid gas made itself noted after various lengths of time. Even in the chronic cases subjective and objective improvement was noticeable almost from the commencement of the treatment, and improvement in regard to duration or intensity or in both. Amelioration of shortness of breath was noted not only during the attacks but also in the intervals, and bodily exertion, as climbing of stairs, could be borne with greater facility. Simultaneously with relief of dyspneic and asthmatic difficulties there was experienced a most beneficial influence on the bronchial catarrh. Only in one case no change was noticed during treatment. In all these cases only a limited number of injections was given. Ephraim observed in some cases that nightly attacks would be prevented when the injections were made during the afternoon; that they would come on, however, when the injections were given during the forenoon.

4. Carbonic-acid Gas in the Treatment of Whooping-cough.—This subject has been treated by me first in an article published in the *New York Medical Journal*, March 9, 1895, and in two communications, which have appeared in the same journal, November 30 and December 28, 1895.

During the spring of 1897 I addressed myself to Dr. Joseph O'Dwyer. He, in a most amiable letter, accepted my proposition to give the carbonic-acid-gas treatment for whooping-cough a trial in the New York Foundling Asylum. The result was published by Joseph O'Dwyer and Nathaniel Read Nor-

ton in their treatise on whooping-cough, which appeared in the fourteenth volume of "The Twentieth Century Practice." During 1897, at the New York Foundling Asylum, 150 cases of pertussis were treated by the carbonic-acid-gas douche. Of the whole number, 143 of the patients showed very marked benefit. The vomiting ceased, even in the severest cases, by the second or third day, the whoop disappeared, and the number of paroxysms was reduced to two and three daily. The seven remaining patients were apparently not benefited; one of the seven was well along in the disease before this treatment was instituted. The duration of the disease, so far as could be determined, was not influenced. Not the slightest ill effect of the treatment was observed. During the administration of the gas the faces flushed decidedly, and this lasted some fifteen minutes. The treatment was given three times daily, some two or three hours after meals. In infants the treatment lasted five minutes at each time; in the "runabouts" ten minutes. The treatment has been the most satisfactory ever used in the institution.

In the month of July, 1898, the treatment by the gas of a large number of cases of pertussis in the New York Foundling Asylum was again commenced. The report will be presented at some future time.

5. Carbonic-acid Gas in the Treatment of Dysentery.—My most satisfactory experience with the gas in this affection I published first in the *Annals of Anatomy and Surgery*, December, 1883, and later in an article which appeared in the *New York Medical Journal*, March 9, 1895. It was only recently, while looking up the whole literature on carbonic acid as a therapeutical agent, that I found in Sobernheim-Lessing's *Handbuch der speciellen praktischen Arzneimittellehre*, Leipzig, 1863, the following information: "Finally the gas exhaled by the mineral springs containing much carbonic acid is used externally against putrid, scorbutical, carcinomatous ulcers. I am constrained also in this place to recommend the carbonic-acid-gas douches into the rectum." For almost fifteen years I had been under the impression of having been the first to recommend carbonic-acid-gas douches in dysentery.

6. Carbonic-acid Gas in Impotence and Some Gynecological Affections.—The first noticeable effect of carbonic-acid baths is a peculiar sensation of warmth, with pricking, especially at the perineum, from where it extends gradually over the whole body, reddening the skin. This effect is most marked on the inner surface of the thighs, on the perineum, on the scrotum, the labia, in short, on all parts which are especially well supplied with sensitive nerves. The frequency of the pulse is at first diminished; after twenty minutes it becomes normal again, and after prolonged stay in the bath it exceeds the normal. During the bath there is an increased desire to micturate, and afterward the amount of urine voided is unusually large. The physiologic effect is, therefore, congestion in the vascular system, and irritation of the peripheral nerve-ends. Carbonic-acid baths have been recommended in affections of the nervous system in general; as, for instance, hypochondria, hysteria, neuralgia, peripheric paralysis, and in combination with gymnastics in disorders of circulation.

The rational application of carbonic-acid-gas baths or douches in the treatment of impotence and some gynecological affections is of great importance. Careful investigations have proved that the effect of carbonic-acid water does not essentially differ from that of carbonic-acid-gas baths, in most cases; moreover, as much or more service may be rendered by the simple gas douche as with either water or gas bath. Physicians at watering-places are aware that men who are easily excited will have erections during their stay in the carbonic-acid water-bath, and that in many the libido becomes markedly stronger under treatment by such baths. It is the peripheric irritation near the sexual organs which increases sexual sensation in men of this class. This erection is especially noted when the rectum is inflated with carbonic-acid gas. Evidently it is due to the innervation, discovered by Fellner, of the rectum by branches of the nervi erigentes. It goes without saying that those forms of impotence which depend on malformations, congenital defects, diseases like diabetes, nephritis, cerebral lues, tabes, and atrophy of the testicles are not amenable to treatment by carbonic-acid gas. Carbonic-acid gas is, however, an excellent remedy in neurasthenia sexualis, in nervous impotence caused by diminished utilization of the capability of the spinal centers, or by disorders of their reflex conduits.

In cases of spermatorrhea, polutiones diurnæ, ejaculatio præcox, in which the nervous weakness depends on morbid irritability of the spinal apparatus for ejaculation, carbonic-acid gas is not to be resorted to; in such cases hydrotherapy and electricity are the means to be considered, because our object here must be to reduce irritability and to improve the power of resistance. It may, however, happen that after the last-named remedies have done their work carbonic acid will be indicated.

In general, carbonic-acid gas is a remedy to be applied in cases of missing erectio and libido not combined with spermatorrhea, in which the difficulty has no other basis than the purely nervous. The

grave forms of impotentia paralytica and psychica are also to be excluded. An exceptionally favorable field presents itself in impotentia senilis præcox.

In the female, conditions of oppression or atonia or torpor of the sexual organs may be relieved by means of carbolic-acid-gas douches, and sterility depending on anaphrodisia may be cured. During sexual excitement a constriction of the vagina takes place by which means retention of sperma is aided. The uterus at these times descends into the pelvis, the os opens, and ejaculates mucus of alkalin reaction from the cervical glands, which secretion acts on the mobility of the spermatozoa simultaneously with the ejaculation, and erection of the lower uterine segment takes place, which erection changes post-cohabitationem into relaxation, whereby the sperma is aspired. The absence of this erection often is the cause of sterility, and in such cases carbonic-acid-gas douches may prove of service. It is well known, however, that exceptionally, women may conceive who experience no erection, no excitement. There are cases in women as well as in men of absence of sexual excitation, in which no benefit can be expected from the application of carbonic-acid gas.

I have found the gas, also, a most reliable agent in the treatment of vaginismus.

Démmé of Philadelphia describes a case of puerperal eclampsia in which the os was rigid and unyielding; it dilated under the influence of the carbonic-acid-gas douche. In another of his cases this douche gave most marked relief in painful labor and seemed to aid dilatation of the os. In a number of other cases he succeeded in rendering labor painless by applying the gas douche to the os for a minute or two every ten minutes. Démmé's experience is easily explained by the fact that carbonic acid produces local anesthesia especially on mucous surfaces; difficult, however, it is to explain why this effect is not generally made use of in midwifery. Scanzoni, in the year 1857, recommended carbonic-acid gas as a means to induce premature birth. Notwithstanding that the prominent gynecologists, Simpson, Hohl, and Gustav and Carl Braun have contradicted Scanzoni and have furnished conclusive evidence that he was in error when he attributed to the carbonic-acid douche the power to cause contractions of the uterus, his assertion is frequently met with in literature. Hohl says that carbonic-acid gas induced into the vagina would be as little apt to cause contractions of the uterus as if it was applied to the abdominal wall. It would require too much space to enumerate here the proofs of this assertion, which are given in the writings of the four gynecologists named. I reported as early as the year 1885 on cases of incessant vomiting in pregnancy in which I had successfully applied the carbonic-acid douche. In a case which I at first supposed to be one of amenorrhea I convinced myself that the carbonic-acid-gas douche applied to either vagina or rectum is not apt to induce abortion. My patient lived in the country. I did not see her for weeks, but when I saw her again she had, according to my instructions, several times a day and every day for weeks in succession applied the douche, part of the time to the vagina and part of the time to the rectum. At this visit I discovered that she was pregnant in the third month. The pregnancy is still progressing. It is true Ephriam applied the carbonic-acid douche to the rectum in a case in which he did not suspect pregnancy, and after the third application abortion took place. Ephriam says that this one case does not prove that the douche was the cause of the abortion.

The apparatus which I employ consists of a bottle holding a pint or more with a wide mouth and a rubber stopper, the latter perforated so as to admit a glass tube, which at the external end is connected with a rubber tube, and at the farther extremity a nozzle to be introduced into the rectum. The bottle is to be filled one-third with water. The glass tube in the bottle is to reach as far down as one or two inches above the level of the water. In the water are put about 6 drams of bicarbonate of soda, and then when everything is ready for inflation half an ounce of large crystals of tartaric acid. If pulverized acid is used the development of the gas goes on too rapidly. The bottle is now closed quickly, the carbonic acid rises through the tube, and inflates the rectum. Démmé's contrivance presents the advantage that it can be carried conveniently in pocket or satchel, and is unbreakable. It consists simply of an India-rubber bag with two openings, the one to serve for attachment of the tube, the other for the introduction of the materials used in generating the gas. This opening is closed by a properly fitting cork.

CLINICAL MEMORANDA.

TWO INTERESTING AND UNUSUAL COMPLICATIONS OF PNEUMONIA.

BY CHARLES J. ALDRICH, M.D.,
OF CLEVELAND, OHIO;
LECTURER ON CLINICAL NEUROLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS; NEUROLOGIST TO THE CLEVELAND GENERAL HOSPITAL AND TO THE CLEVELAND CITY HOSPITAL.

CASE I. *A Rare Complication of Pneumonia Consisting of an Ascending Neuritis of the Phrenic Nerve with Extension to the Brachial Plexus. Recovery, with Permanent Atrophy of a Part of the Shoulder and Arm Muscles.*—J. S., a healthy farmer, forty-three years of

age; previously robust, and from a stanch family. On April 6, 1888, I was called to see him, and found him suffering from an acute attack of pneumonia of the right lung. It was ushered in by a severe chill and much vomiting. The latter symptom was a pronounced feature during the first week of the disease. He was jaundiced on the fifth day of the disease, and after the first week presented typhoid symptoms—great depression, dry, brown tongue, diarrhea, and muttering delirium. The spleen and liver were both enlarged. At the end of the third week resolution was slowly advancing, and his temperature, diarrhea, and delirium were disappearing, when he was suddenly attacked by severe hiccough. It was constant and violent, and appeared as if in one act of hiccough the diaphragm was rapidly contracted and relaxed two or three times in the space of time usually occupied by an ordinary spasm.

In the face of blisters, galvanism, tight bandaging, snuff, morphin, and the whole gamut of antispasmodics, with little intermission, the hiccough persisted five days and five nights. With little hope we watched him grow weaker and weaker under the awful strain of this "double-barreled" hiccough, as Dr. Latta of Goshen, Ind., aptly called it. On the sixth day of the hiccough it was noticed that the stools were clay-white, and it was decided to give him calomel. An acquaintance with his habit of taking 10 to 20 grains of the drug at a dose in health encouraged me to give the massive dose of 1 dram, divided into three parts, administered at intervals of two hours. The remedy opened his bowels. The hiccough stopped before morning, and he began a tedious recovery. No ptyalism was produced. Several days after the hiccough had ceased he began to complain of severe pain in his right shoulder, and a distinct loss of power in the arm and shoulder-muscles was apparent. Hot applications eased the pain, but the whole region was very sensitive to touch.

Examination four months later revealed an appreciable atrophy of the trapezius, spinati, deltoid, and supinator longus muscles, and a noticeable weakness of the whole scapho-humeral group. Two years later the shoulder had not regained its wonted power and contour.

This rare complication of pneumonia was not then recognized as a neuritis of a part of the bronchial plexus by extension from an ascending inflammation of the phrenic nerve. The course of the paralysis and atrophy was characteristic of a brachial neuritis, but its remote relation to the inflamed area and the writer's deficient knowledge of neuritis ten years ago caused him to fail to recognize the true nature of the case.

Hiccough is produced through the agency of the phrenic nerve, and may result from irritation of the diaphragm, peritoneum, or mucous membrane of the alimentary tract. The phrenic has its origin mainly from the fourth cervical nerve, but usually receives contributing filaments from the third and sixth cervical nerves. Hoover and Howard[1] in their excellent paper on "Tropical Abscess of the Liver," state that "phrenic-nerve irritation, besides the local pain, often manifests itself in regions which are supplied by nerves having a common or contiguous origin with the phrenic." Rouis collected 163 cases of liver abscess, in 28 of which there was a history of pain in the region of the shoulder, and he details a case which affords as good evidence as mine of the possibility of an ascending neuritis of the phrenic. A man, aged twenty-three years, had an abscess of the liver which opened spontaneously in the epigastrium. Pain was persistent in the deltoid muscle until the rupture. He lost power in the deltoid, and six months later the muscle was much atrophied. I really doubt the existence of a genuine ascending neuritis of the phrenic nerve, but would rather suspect a neuromyelitis. My reason for this faith is that a patient with neuritis usually recovers, whereas a myelitis always cripples more permanently.

[1] *Amer. Jour. of the Med. Sciences*, vol. 114, pp. 150–263.

CASE II. *Inflammation of the Right Parotid Gland Complicating a Right Pneumonia; Suppuration of Gland; Operation and Recovery.*—Osler[1] says that parotitis, as a complication of pneumonia is an "excessive rarity." He refers to a case mentioned by Traube, and reports the only case that he has ever seen. Dr. A. J. Hamilton[2] has also reported a case. Osler's case was fatal. Hamilton's patient recovered. These are the only reports of cases that I have been able to find, and the following one embraces my entire experience with this very rare complication of pneumonia:

J. H., male, single, white, aged twenty-two years; a music printer by occupation. Previously healthy; good family history. I first saw him in private practice, February 18, 1894. He had experienced a severe chill the night preceding my visit, and had developed a dry cough and severe pleuritic pains in the right side. I found him with a temperature of 104° F., pulse 120, and respiration shallow, hurried, and very painful. The cough was constant and distressing. Physical examination revealed the typical signs of a severe right lobar pneumonia, with a decided pleural inflammation. It proved to be a "frank" pneumonia, and pursued a severe but natural course. The tongue was constantly dry, and the pleuritic pains radiated to the back and right shoulder.

Resolution was well advanced on the twelfth day, when he was seized with severe pain in the region of the right parotid gland. I was sent for and found the gland hot, swollen, and tender. His temperature had risen from 100° to 105° F. He had successive chills and suffered great pain. His temperature for the following four days rarely fell below 104° F. He was evidently a very sick man, and Dr. A. J. Cook was called in council. We were in doubt as to the presence of fluctuation in the greatly swollen gland, but were sure that the patient ought to be sent to a hospital. He was sent to St. Vincent's Hospital on the following day and placed under the care of Dr. N. Stone Scott, who made multiple deep incisions into the inflamed gland and scraped out a quantity of gangrenous gland tissue, and irrigated and packed the cavities. The outlook was indeed gloomy, but to our surprise and gratification he made a prompt rally and an uneventful recovery.

ENORMOUS HYPERTROPHY OF THE KIDNEYS AND DILATATION OF THE BLADDER AND URETERS IN A CHILD THIRTEEN MONTHS OF AGE. SUPPURATIVE ORBITAL CELLULITIS.

By HENRY B. HEMENWAY, M.D.,
OF EVANSTON, ILL.

CASE I.—On May 22, 1893, I was called by Dr. Wm. A. Phillips to assist in the delivery of a breech-presentation case. The child was large, and the mother was rather fleshy, making delivery difficult. Both mother and child did well under Dr. Phillips' care, and I knew nothing more of them until July 11th following, when I was called to see the baby in the absence of Dr. Phillips from the city. I found at that time a well formed female child, with skin slightly yellow, and abdomen prominent. Percussion showed dulness in the lower portion of the abdomen and around the navel. She was peevish, frequently vomited food, and her bowels were inclined to be constipated. Urine was passed frequently, but in what quantity I could not determine.

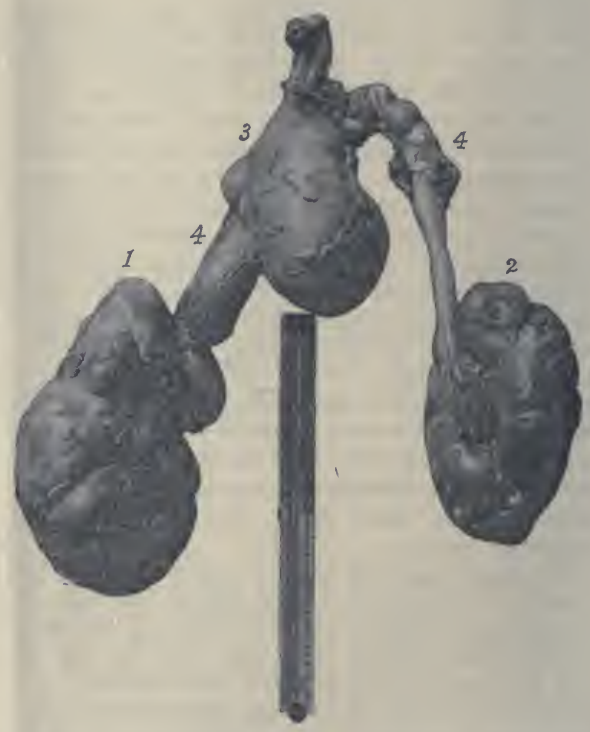
Considering that the trouble was probably due to obstruction of the portal circulation and indigestion, treatment was directed toward improving these conditions. I understood that from the time the child was born this general treatment had been pursued. Nevertheless, the abdomen continued to increase in size, and the child was evidently losing strength. Respiration and heart action were rapid. Finally, July 23rd, at my request (for the family had been offended on account of the doctor's absence from town, and a misunderstanding with his substitute,) Dr. Phillips was called in consultation. After examining the little patient we retired to consult. We agreed on the probable diagnosis, and on the past treatment. As to prognosis we were not sure. We agreed that she might drop off in a day or two, or she might recover. The rapid shallow respiration, and rapid feeble pulse, irregular as to rapidity, were the most serious symptoms. Neither of us could understand why we could not reduce the size of the abdomen with laxatives. While we were consulting we were informed that the patient had ceased breathing. So far as we could see, when we had been examining her, there had been no change for several days. There was no convulsion.

The autopsy, 5½ hours after death, showed slight rigor mortis. There was moderate icterus. Umbilical hernia, not protruding. Subhemorrhagic spots on left lower leg. Incision through $\frac{1}{32}$-inch subcutaneous fat was followed by the escape of abdominal fluid—ascitic—which was icteric in color. There was no protrusion into the umbilical hernia, which was produced by the ascitic fluid being crowded into the weakened area. The bowels were normal in appearance, but the entire abdominal cavity was filled with the cystic kidneys and bladder, as shown in the accompanying photograph. These we did not open, as Dr. Phillips desired to submit them to an honored member of the profession for careful examination. I regret to say that the professor referred to died before making a report.

My own theory of the case is that there was a membranous obstruction to the exit of urine from the left ureter. Gradually this membrane was pushed forward until it interfered with the exit of urine from the ureter. In this way there was a constant distention of the bladder, left kidney, and ureter, while urine was discharged from the right side when the tension was great enough to force it by the obstruction. It will be noticed that the relative size of the left kidney is greater than appears from the photograph, it being further from the camera. The rule shown is a foot long, half closed. The left ureter is raised upon a piece of pasteboard. The left kidney was about 5 inches long.

Family History.—The father, aged forty-five years, is of bilious temperament. His urine is generally scanty and highly colored with urates. His lungs were "weak"

FIG. 1.



Hypertrophy of the kidneys and dilatation of the bladder and ureters in a child thirteen months of age. 1. Left kidney. 2. Right kidney. 3. Bladder. 4. Ureters.

when he was young. His father died at the age of sixty-seven of consumption, and his mother of "grip" at sixty-two. He has two sisters, aged forty-seven and forty-three years, both in good health. One half-brother died at the age of forty-four of Bright's disease or diabetes. The family used the terms synonymously. His father died of the same disease.

The mother of the patient is aged forty-three years. Health good. Her father may have died of kidney disease, but his final illness was the result of an injury. Mother living and in good health. The patient's mother had seven brothers and one sister, all living and in good health. The parents of our patient had had six children, the oldest being about nineteen years old at the time of the

death of the baby. None of the other children has ever shown evidence of kidney disease.

CASE II. *Suppurative Orbital Cellulitis.*—May 20, 1896, I was called to see Miss M., Irish, aged sixteen years. Thursday, May 18th, she suffered from toothache in the left upper first molar which was badly decayed. She went to a dentist who advised that the tooth be pulled, but she objected. Friday the tooth continued to ache for which she used some "drops" purchased at a drug-store. When I first saw her, at 2 P.M., Saturday, there was marked exophthalmos of the left side, the result of a general orbital cellulitis. The house was small, crowded, and uncleanly. I was not prepared for such a grave case, and so advised that she be sent to the Illinois Eye and Ear Infirmary without delay. Before supper time she was there, and had had the offending tooth extracted. The surgeon in attendance also made an incision into the upper lid. The following Thursday, May 25th, at the earnest request of the parents, who were not pleased with the treatment, I visited the hospital, and there met the surgeon. He is a fine operator in eye surgery generally, being both rapid and neat. This case, however, being out of the ordinary line seemed to stagger him. He attempted to enlarge the external commissure and injected a bichlorid solution into the opening in the upper lid. He suggested to the interne something about an opening into the antrum, but he did not make it nor was one ever made.

June 2nd the patient was brought home and again placed in my charge. There was at that time a profuse discharge of offensive pus. Twice each day the cavity was washed out with a solution of peroxid of hydrogen, or of thymenthol. After a few days it became possible to force the injection into the nasal cavity from the orbit. Two spontaneous openings had occurred, assisted at the last by the knife, one through the lower lid near the inner canthus, the other near the external canthus in the upper lid. The eyeball had evidently broken soon after she had entered the hospital. Gradually the amount of discharge decreased and I was able to detect a sequestrum in the ethmoid region. This I wished to remove in September, but the patient was feeling so much better that she declined further treatment.

I met her recently on the street. The opening in the upper lid still discharges a small amount of pus. The eyeball is apparently about one-third as large as its mate. The cornea is hazy.

Why this abscess should have been opened at its *highest* point I never could understand. Good drainage is absolutely essential in all cases of suppuration. After the case came back into my hands, there was no apparent need for further openings. Those existing, though not ideally located, served well, and it was no longer a question of saving the eyeball even. At first, so severe was the inflammation, I had little hope of saving the sight, and even feared for the patient's life. I regret, however, that I did not at once make a large opening at the bottom of the orbit. Had that been done, and the orbit antisepticized, I think the eyeball, and possibly some sight might have been saved. A preexisting catarrh evidently had some bearing upon the case, and had the patient permitted the removal of the sequestrum doubtless the fistula would long ago have healed.

MEDICAL PROGRESS.

Pulmonary Tuberculosis Treated with Large Doses of Creosote.—LAMPLOUGH (*British Medical Journal*, May 28, 1898) records the results of treating one hundred cases of phthisis with large doses of beechwood creosote. He was surprised to find that the toxic symptoms which are said to follow the administration of large doses were absent in nearly every case. The method of its administration is as follows:

A few minims of equal parts of creosote and alcohol are dropped into an oronasal respirator, or the patient is treated in a creosote chamber. Five minims of creosote thoroughly mixed in 2 drams of cod-liver oil are administered three times daily after food. Five minims of creosote are to be added every other day to each dose until a maximum of 40 minims three times a day is reached —in about two weeks. If the patient is unable to take cod-liver oil the creosote should be given in 20 minims each of alcohol and compound tincture of gentian and 30 minims of fluid extract of licorice. If the creosote causes a burning sensation this may be at once relieved by sucking a bit of lemon or swallowing milk or water. This symptom seemed to be no more troublesome after a large dose than after a small one. Out of a hundred cases where this creosote was given in these large doses, only five patients were unable to continue taking the drug. Two of these had such advanced lesions that they died in two weeks after admission to the hospital. A third objected strongly to the taste and smell of creosote and refused cod-liver oil, whether alone or mixed with extract of malt. The other two patients were able to take cod-liver oil, and it was given to them pure. Of the 100 cases 62 had disease of both lungs; nevertheless, 68 patients were either partially or entirely relieved of their symptoms and gained in weight, an average of four pounds each in about two-months' treatment. The physical signs also improved greatly in many cases but not in comparison to the improvement in the symptoms.

Although creosote is by no means a specific for pulmonary tuberculosis its good effects are beyond question and the harmlessness of large doses is clearly brought out by Lamplough's daily observation of these patients. So far as could be ascertained from frequent and careful examination of the urine creosote has no injurious effect upon the kidneys. These large doses are well borne by children. Three of the patients treated were between five and seven years of age. In two of them the disease was marked. They all took 30 minims of creosote three times a day with decided improvement and no signs of toxemia.

Having compared the objections raised against the administration of beechwood creosote in phthisis with the results obtained at this hospital by treating 100 cases with this drug, the writer suggests that the following points are worthy of consideration and further investigation:

1. The best beechwood creosote can be given with

benefit, in amounts varying from 120 to 240 minims daily, in cases of pulmonary tuberculosis.

2. The drug is best administered in cod-liver oil or in a spirituous solution, and in some cases the "creosote chamber" or oronasal inhaler may be ordered in addition, with advantage.

3. The dose should be smaller at first, but it can be rapidly increased to 40 minims three times daily for an adult. In 3 cases doses of 30 minims three times a day were well borne by children.

4. Large doses rarely cause any gastric disturbance; on the contrary, the appetite is frequently increased, symptoms of dyspepsia disappear, and cod-liver oil is more easily assimilated. The cough, expectoration, and night-sweats are diminished, and the physical signs improved.

5. Owing to its disinfectant action in the alimentary canal the drug probably diminishes the risk of tuberculous enteritis by auto-infection when patients swallow their sputa, but owing to the increased peristalsis, which is created by creosote, it is usually contraindicated in cases where the ulceration is already advanced.

6. The drug does not tend to cause hemoptysis, but rather to prevent its recurrence.

7. Creosote does not irritate the normal mucous membrane of the genito-urinary tract.

8. Owing to its extremely small cost pure creosote can be given to a much larger number of patients than the carbonates of creosote and guaiacol, which respectively cost four times and twelve times as much as the older drug.

Gastric Ulcer Successfully Sutured Twenty-four Hours after Perforation. — CABOT (*Boston Medical and Surgical Journal*, August 11, 1898) reports a case in which he was able to find and suture a perforation in the stomach of a woman of about thirty years of age. The opening was in the lesser curvature and was surrounded by a fibrinous exudation. The indurated area marking the base of the ulcer was about an inch in diameter. This he dimpled into the stomach so that the Lembert sutures passed through healthy tissues. Two rows of stitches were taken. The perforation seemed to have occurred about twenty-four hours before the operation, but no portion of the stomach-contents had escaped; at least none could be detected in the peritoneal cavity, although a large quantity of gas had escaped from the stomach and obscured the liver dulness. The abdomen was irrigated with a salt solution and carefully wiped out. The patient made a steady recovery, the most annoying symptom being excessive flatulence. No food was given by the mouth for several days after the operation. A small gauze drain was used, which was pulled out on the fifth day.

Reason for the Increase of Cancer.—WILLIAMS (*Lancet*, August 20, 1898) laments the fact that so little attention is given by physicians to the constant increase of cancer. In England and Wales, in 1840, cancer caused 1 in 129 deaths. In 1896 the deaths due to it numbered 1 in 22 of the total mortality. Thus the proportionate mortality from cancer is now four and a half times greater than it was half a century ago. In this respect its position is unique, for no other disease can show anything like such an enormous increase.

Probably no single factor is more potent in determining the outbreak of cancer in the predisposed than high feeding. The consumption of meat has been increasing year by year, until now it has reached 131 pounds per head per year in England and Wales, which is more than double what it was half a century ago, when the conditions of life were more compatible with good living than they are to-day. When excessive quantities of such highly stimulating forms of nourishment are ingested by those whose metabolism is defective it seems probable that there may thus be excited in those parts of the body where vital processes are still active such excessive and disorderly cell proliferation as may eventuate in cancer. No doubt other factors cooperate, especially deficient fresh vegetable food and lack of sufficient exercise.

A remarkable fact about increasing cancer mortality is that is has affected males to a much greater degree than females. Thus while the cancer mortality for males from 1851 to 1890 shows an increase of 167 per cent., the increase for females has been only 91 per cent. Williams explains this upon the ground that modern city life is compelling many more men than formerly to live the inactive overfed existence which has for a long time been the lot of most women. He believes that it lies in the power of physicians and the laity to greatly reduce the occurrence of cancer—perhaps to abolish it altogether—by calling attention to these causative factors, and insisting upon the avoidance of gluttonous habits of life.

THERAPEUTIC NOTES.

Migraine Due to Muscular Gastric Atony.—DOL (*Gaz. Heb. de Med. et de Chir.*, June 5, 1898) says that it is well recognized that digestive troubles often cause vasomotor disturbances, as evidenced by flushed face, cerebral congestion, and other symptoms. There are other symptoms of a nervous character simulating an attack of migraine. Such attacks seem to occur in connection with muscular gastric atony of the stomach. There are two types of this. In one of these there is the sudden onset identical with an attack of migraine but always occurring after a meal. The other type, less violent, is characterized by an intense pain after meals. It possesses some of the points of migraine. The treatment should accomplish the complete evacuation of the stomach and intestines either by vomiting and catharsis or by lavage. Prophylactic treatment in order to cure the atony of the stomach should always follow the measures designed for temporary relief.

No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK,
AND NOS. 706, 708 & 710 SANSOM ST., PHILADELPHIA.

SATURDAY, NOVEMBER 5, 1898.

A NEW YORK medical contemporary states that the Emperor of China is dying of systemic poisoning. As, according to the London *Times*, the physician of the French Embassy who examined him reported that he was suffering from albuminuria, incipient phthisis and great debility an appeal to poison in the case, we humbly submit, would seem scarcely called for, and the slur at the Empress, that the *Record* makes, unfounded as far as the evidence goes. It is usual to find the deaths of prominent people, when due to obscure disease, attributed in history to poison, especially if they seemed to occur at an opportune time for some one else, but it is time that this sort of thing should cease now that advances in medicine have made it possible to diagnose diseased conditions with accuracy. In the present case certainly, with a patient suffering from serious pathologic conditions of two important organs, there should be no medical countenance of rumors as to poisoning without authoritative and detailed substantiation of the reports.

A NUMBER of lay contemporaries, and we are sorry to say even some of the medical journals, mentioned the first victim of the plague as *Dr.* Barish. He was not a medical man but only a hired assistant in the laboratory, who made media, tended to the animals, and kept the laboratory in order. It is in such men particularly, ignorant as they are, and incapable of being impressed with the seriousness of the dangers they run, that familiarity begets contempt, until finally some neglect of necessary precaution leads to an outbreak of disease. Under present conditions the presence of such comparatively untrained assistants is indispensable in laboratory work, so that there is absolute necessity for such legal regulation of experimentation with epidemic disease as we insisted on editorially last week. Dr. Müller owed his infection, it would seem, to his voluntarily attending Barish medically, though he knew that he probably had to deal with the most infectious form of the disease, the pulmonic type.

Professor Nothnagel has received a great deal of unenviable notoriety in the matter, though his only connection with it was the circumstance that the experiments were being conducted in the laboratory of his clinic. Dr. Müller, who has been one of Professor Nothnagel's clinical assistants for some years, was the clinical member of the Austrian Plague Commission which went to India a year ago last spring. He brought home the cultures with him and not unnaturally used the laboratory he had at hand. Laboratory room is not over generously supplied in Vienna, especially in the General Hospital. Workers must be satisfied with the least possible conveniences, in cramped quarters. With them scientific enthusiasm must make up for the tempting airiness and roominess of the modern laboratory of research.

THE third part of the address of Sir William Crookes, at the recent meeting of the British Association for the Advancement of Science, entitled "The Position of Psychical Research," contained statements which, if emanating from any other man of equal eminence in the scientific world would have caused unbounded surprise. It was, however, known to many that thirty years or more ago this renowned physicist published an account of experiments which he believed tended to show that outside our scientific knowledge there exists a force exercised by intelligence different from the ordinary intelligence common to mortals. The fact that he is

now President of the Society for Psychical Research indicates that his interest and belief in such a force has not abated. Despite this, it must be reckoned an epochal date when the president of a society, numbering in its membership more pure scientists than any other in the world, has the temerity to assert that telepathy is based on the fundamental law that thoughts and images may be transferred from one mind to another without the agency of the recognized organs of sense—that knowledge may enter the human mind without being communicated in any hitherto known or recognized way. The speaker made no explanation of the foundations for his belief, and gave scarcely a reason or argument for their validity, save to point one or two analogies and to restate an hypothesis. This hypothesis, *viz.:* that the dendrites of neurons and the terminal arborizations of neuraxons do not actually touch, but are separated by a narrow gap which widens in sleep, while it narrows almost to extinction during mental activity, has been very widely discussed by neurologists and physiologists during the last few years. To-day, it is impossible that there exists six leading neurologists in the entire world who believe that the "movements of the neuron" is even a working hypothesis to explain neural and mental dynamics. This part of this noteworthy address will probably be read with trepidation and pain by all honest scientists, save a few who pose in the mantle and cling to the edges of the Society for Psychical Research.

COLONEL WARING'S DEATH.

IN the death of Colonel George E. Waring, New York City loses one of her great citizens; the country a man who can ill be spared in the presence of the great questions in civic and military sanitation that face our government at the present time. Modern applied sanitary science contains some extremely interesting and practical chapters that will keep the name of Waring alive during future generations. What he accomplished at Memphis, Tennessee, and in Central Park, New York, at a time when sanitary science was but just emerging into life, remain as monuments to his skill and intelligence. His organization of the street-cleaning department of the City of New York was enough of itself to make him famous and to give him a prominent place in the annals of public health at the end of the Nineteenth Century. By it he has conferred a boon upon the city the extent of which even its most intelligent and vigilant citizens scarcely realize. The methods he introduced will continue their benefits for future generations.

Though his age might well have justified him in asking to be excused from active and exacting duty in the public service, he accepted without hesitation the President's invitation to investigate the condition of Cuba and especially of Havana, with the idea of suggesting the sanitary measures necessary to provide healthful places of residence for American citizens and, especially, sanitary quarters for American troops, who will have to be maintained there probably for some years. He was returning home with the data collected that would be necessary for his preliminary report in the matter, when the first symptoms of his fatal illness developed. It seems almost like the irony of fate after his successful battle with yellow fever in other places that now when ready to put the finishing touches to the work by uprooting the evil at its very source and so prevent all future epidemics of the disease in our country he should be stricken down and, with resistive vitality lowered by age and recent exhausting work, prove an easy victim. All honor to him as a champion of humanity against dirt and disease.

His death leaves a gap which will not be easily filled, but the Government must face the great problem of the sanitation of our new possessions, and this latest sacrifice is but another forecast of what a cost of life it may involve.

PROFESSOR VIRCHOW AND THE UNITY OF LIFE—A PROTEST.

WE recently reviewed Professor Virchow's Huxley Lecture in that spirit of enthusiastic regard with which we are sure his distinguished English audience must have received it, and with which the medical world must ever welcome the great sayings of the father of modern pathology. This week we permit ourselves, in the reverential spirit of disciples of the man who above all others taught medical men to think and seek for themselves and to accept nothing on the *ipse dixit* of a master, to discuss some of the propositions it contains.

Professor Virchow thinks (we quote from the address as published authoritatively in the *British Med-*

ical Journal; as it was delivered in English we have the speaker's own words) that "In a medical school where the teaching is almost entirely concerned with human beings we might put this sentence at the head of the lesson: 'The organism is not an individual but a social mechanism.'" He said just before, "The life possessed by the higher organisms is not a single life. . . . Each constituent part of a living organism has its special life, its *vita propria*. . . . As regards materialistic construction man and the higher animals and plants are no unitary simple beings. . . . If they possessed but one single power which set all their parts in action it would be impossible to understand how the special kind of activity which each one of these organisms exercises in its individual way comes about. . . . How can a single power, whether we call it in the spiritualistic sense spirit, soul, spiritus rector, or, in the physical sense, vital force, or electricity, build up such diverse organisms? . . . The first requisite for a correct interpretation (if such a collective being is analyzed) is that one should *discard the fabled unity* (italics are ours) and should regard the single parts, the cells, as the factors of existence."

We have not quoted a series of connected passages because space forbids it; on the other hand, we have not, we can confidently say, wrested any of the sentences from their author's meaning in separating them from their context. The series of sentences quoted represents a materialistic view of man as a living organism which we feel sure is not shared by the majority of, at least, English-speaking medical men and scientists. These views will receive widespread circulation in our medical journals and will lead to false assumptions as to the stand modern medicine is taking in the matter, if they are allowed to circulate without a word of protest.

The human organism *is* "a social mechanism," all the cells of which are in health coordinated by that mysterious force we call life; not the multiple life of the individual cells but the unitary principle which, the moment previous to sudden traumatic death, made the now insentient mass of lifeless cells living, sentient, conscious, thinking man. We do not know *how* "a single power sets all the various parts", the multitudinous cells, in action, but we do know that man is a single simple being, with a single principle of life, and not merely a congeries of cells more or less fortuitously bound together.

Medical men generally (we speak at least for our English-speaking brethren) believe this because they believe in the existence of something beyond and above matter, spirit, and in the existence of a spiritual principle of life in man, the human soul. They have evidence for their belief in the existence of their own consciousness which is surely not a function of matter, in the realization of their powers of reasoning which is indubitably not merely material. The principle of life that originates these higher functions must be of such a nature as to produce them and must itself be superior to matter.

Modern science, and especially the sciences that are most closely related to medicine, are getting farther and farther away from the position that would explain all vital phenomena on merely materialistic, *i.e.*, chemico-physical grounds. Spontaneous generation is gone, thanks not a little to Virchow's own work. The supposed simple processes of endosmosis and exosmosis in metabolism and of simple oxidation in tissue waste and repair have given place to complicated intracellular processes dependent on essential cellular activity brought into play by that mysterious force called life. A very interesting commentary on this question of vital force and of the unity of organismal life from the physiologist's point of view may be found in "Vitalism," an article in the *Nineteenth Century* for September by Mr. Haldane, lecturer on physiology at Cambridge, England.

Science has been giving us the demonstration, too, that behind this vital activity in individual cells there is a force that makes for the conservation, and during the developmental period for the proper development of the *whole* organism. If in certain of the lower forms of life during the embryonic period, one-half of the cells that make up the embryo be removed, the other half will develop sufficiently to make up for the cells that have been removed and the resulting organism will be perfectly normal. In certain of the lower animals too, removal of a limb is followed by the growth of a member to replace it which exactly corresponds to the one that was removed. We have in these facts surely not the result of multifarious individual cellular activity but the evidence of a principle of life, higher

than mere cellular activity, pervading the whole organism coordinating cellular energy and providing for the protection and conservation of the *whole* being.

Professor Virchow himself says in this Huxley lecture, "The necessity for a single basis of all vital manifestations remains. It is a question which is not alone of great theoretical interest, but it has become an indispensable foundation for practical work and particularly for medical practice." Here is the keynote of the matter for the practical physician and for our present-day therapeutics. For changes in cells, at least as far as regards the gross alterations that constitute the only cell changes we know so far, we are able to do very little. Modern therapeutics is just beginning to make use of the products of cellular activity in order to restore or replace the functions of damaged cells. As yet, however, this form of therapy is extremely limited in application. Practically, all of our pharmaceutics is dependent on the principle that there is a single basis of life and that the organism is a compensatory mechanism. The results of this system of therapy, while not all that might be wished, have been such in the hands of our great practical clinicians as to justify the conclusion that there is a great truth underlying it.

The most striking thing in modern medical practice is the influence of mind over body, of vital force above and beyond any individual cellular activity, that must be reckoned with in all rational treatment of disease. Medical realization of the influence of this higher force has been growing clearer not dimmer in recent years. It is evident then, that the medical profession is on scientific grounds drifting away from, not toward any opinion that would deny the essential unity of organisms, especially of man.

ECHOES AND NEWS.

Smallpox at Norfolk, Va.—An epidemic of smallpox is announced at Norfolk, Va. Fifteen new cases were reported on October 31st.

The John Blair Gibbs Hospital.—The Government has very appropriately commemorated the sacrifice of the first American soldier on Cuban soil by naming the general hospital attached to Camp Hamilton at Lexington, Ky., the John Blair Gibbs Hospital.

Tetanus Recovery after Antitoxin Treatment.—The patient at Passaic, N. J., who suffered from tetanus and was recently treated by the injection into his brain of antitoxin serum continues to improve. He has become so well that it has seemed wise to apply skin-grafting to the injured leg.

A Public Hospital at Troy, N. Y.—The formal opening of the Samaritan Hospital at Troy was celebrated October 23d. This new hospital is modern and complete in every detail. One of the wise provisions connected with the management of the institution is that by which any private patient who enters the hospital has the privilege of choosing any medical attendant he desires, the hospital thus being free to the profession as well as to the laity.

Medical Society of the State of New York.—The Business Committee of this Society announces that the next meeting of the Society will be held at Albany, January 24, 25, and 26, 1899. The committee consists of Dr. Willis G. Macdonald, Albany, N. Y., Chairman; Drs. Edward B. Angell, Rochester, N. Y., and James M. Winfield, Brooklyn, N. Y. Members desiring to present papers will please notify the chairman of this committee.

Obituary.—Dr. Francis L. Haynes died from embolism of the brain at his home in Los Angeles, Cal., October 19, 1898. Dr. Haynes was graduated from the University of Pennsylvania in 1870, at the age of twenty years. After serving as interne in the Episcopal Hospital, Philadelphia, for eighteen months he began the practice of medicine in Philadelphia where he remained till 1887, when he removed to Los Angeles and became Professor of Gynecology in the University of Southern California, hoping that a change to a milder climate might improve his health, which had become impaired.

Dr. Guiteras to Go to Cuba.—It is generally understood that Dr. John Guiteras, the great yellow-fever expert, will resign the chair of pathology in the University of Pennsylvania at the end of the academic year and with his family go to Cuba. Dr. Guiteras has been tendered the chair of practice of medicine in the University of Havana. He will be accompanied by several other medical men of high repute who are interested in Cuban affairs. It is Dr. Guiteras' intention to enlarge the medical course at the University of Havana and place it on a footing with similar courses in this country.

Christian Science Malpractice.—The facts connected with the treatment of Harold Frederic by the Christian-Science woman prove to be more startling than the first reports indicated At the coroner's inquest the woman admitted that she had not diagnosed Mr. Frederic's "material" sickness; that she could not describe his physical condition, and that she did not allow her patients to follow doctor's orders. Moreover, she confessed to having taken her patient for a drive only a short time before he died, of heart disease, and did not know that it was the worse thing she could have done for him.

Medical Students in German-Speaking Universities.—In the last issue of the *German Universitätskalender* the number of students of medicine in the several universities using the German language is given as follows: Munich,

1416; Vienna, 1192; Berlin, 1090; Würtzburg, 680; Leipzig, 630; Freiburg, 552; Kiel, 428; Graz, 417; Erlangen, 414; Breslau, 364; Zürich, 340; Bonn, 337; Strassburg, 324; Griefswald, 323; Tübingen, 278; Marburg, 274; Heidelberg, 272; Geneva, 270; Königsberg, 249; Halle, 245; Giessen, 240; Göttingen, 225; Jena, 222; Berne, 189; Lausanne, 145; Basel, 141; Rostock, 99. Total, 11,376.

Mental Pressure in Our Public Schools.—President Schurman, in his recent address at the opening of the fall semester at Cornell University, makes the statement that the age of freshmen at entrance has been falling continuously for three years, although the standard of requirements for admission was at the same time continuously rising. "The average age of Cornell freshmen was nineteen years and eleven months in 1895–96, nineteen years and eight months in 1896–97, and nineteen years and seven months in 1897–98. This seems to show," continues Dr. Schurman, "that the high schools of the country are quite rapidly increasing in efficiency." It would be interesting and valuable to know also the relative physical condition of these youths compared with their predecessors.

Spread of the Bubonic Plague.—The sudden appearance at Vienna of the bubonic plague and its deadly work there, discussed editorially in our issue of last week, has centered no little interest upon the possibilities of its more widespread development. If it has awakened increased vigilance in quarantine circles it is well. A recent cablegram from St. Petersburg announces that the epidemic now prevailing at Samarkand—a large commercial city of Turkestan—is the true plague, and that the mortality is high. The arrival at San Francisco, October 28th, of a French vessel from Hong Kong, infected with bubonic plague is also reported, the captain and one seaman having died of that disease during the voyage, August 20th and September 20th respectively.

Medical Nomenclature.—Under this heading the *Medical Record*, October 29th, remarks: "To the reader or hearer who has some regard for accuracy in the formation and use of words such combinations as 'radiograph' is apt to give a shock. . . . . Of late the much more appropriate term 'skiagraph' has supplanted it to a great extent." The latter term was originally suggested in the MEDICAL NEWS, February 15, 1896, by Dr. Cattell, in one of the earliest accounts of the Röntgen-ray published in this country. The MEDICAL NEWS has consistently used the word since that date. It is gratifying to have the assurance that it is supplanting the monstrosity "radiograph" and that this tardy recognition of its merits by the *Record* gives earnest of the latter's influence in bringing it into more general use.

Sick Soldiers from Porto Rico.—The Massachusetts hospital-ship "Bay State" arrived at Boston October 28th from Porto Rico. The ship carried 133 on her sick-list, mostly men of the Sixth Massachusetts Regiment. Of this number thirty are very ill. Two men, Sergeant William E. Watters, Company E, of Framingham, and Paul T. French, Company M, of Milford, died at sea. Private French was buried at sea, and the body of Sergeant Watters will be turned over to his relatives. The United States Army hospital-ship "Missouri" arrived at New York October 29th from Porto Rico with 271 sick and wounded soldiers, most of them suffering from malarial fever, typhoid fever, or dysentery. L. Burton Bradish, Corporal, Company A, Third Illinois, and Henry M. Morrison, private, Company H, Fourth Ohio, died; the former was buried at Mayaguez, the latter at sea.

Effects of Electricity upon Plant-Life.—In the light of the views promulgated recently by Sir William Crookes it is interesting to note the results of some practical experiments demonstrating the fertilizing effect of electricity in plant-life. Dr. Lemström, aided by Baron Hisinger, a landed proprietor of Finland, has been engaged in experiments on growing plants since 1885. Six fields, each fifty meters in extent, were devoted to these experiments, three being subjected to electricity, and three used as control-areas. The benefit of the electricity was marked; there was found an increase in the seeds of at least 40 per cent.; in the roots from 25 per cent. to 75 per cent., depending on the kind of plant and on the nature of the soil; in beans 75 per cent., in strawberries and raspberries as high as 75 per cent., the time for their ripening being advanced at least one-third. Either the gases in the air are transformed by the electricity into ozone and nitric oxids, which, being heavy, fall down upon the plants and increase the activity of their vegetation, or the electricity induces the juices of the plants to ascend more rapidly in their capillary tubes. Though much has yet to be explained, the method is ready to be used for practical purposes. The author this summer carried out experiments in Finland on some especially interesting plants. Of these, the tobacco plant did not yield, in earlier experiments, to the favorable influence of the electric currents, through want of water.

Sanitary Report from Havana.—The following report for the week ended Thursday, October 20th, by the local inspector, Dr. Brunner, has been forwarded to the Surgeon-General of the Marine Hospital Service: The temperature for the past week has been intolerably warm; the rainfall has been excessive, especially during the last three days, when certainly more than five inches must have fallen, the downpour extending into the nights, which does not often occur here. The neglect of sanitary matters still continues; the streets and public markets reek with filth, and the paved streets need repairs to prevent the collection of storm water and surface filth. There were six deaths from yellow fever, which are three less than the preceding week; four of these deaths occurred among the Spanish soldiers. One of the deaths was credited to borras fever, which, in my opinion, is fatal yellow fever among the Cubans. There was a slight falling off in all the other fevers prevailing here and the total deaths show a decided decrease. The two deaths from beriberi occurred among the Chinese population. The American bark "Maryland" reported by letter and cable as being infected with yellow fever is still in port, but is ready to leave for Baltimore after pro-

ceeding to Tortugas for disinfection. While there are not many known cases of yellow fever, yet on account of the extremely hot weather and the continuance of the rainy season, I would recommend that the close quarantine season be extended from November 1st to November 15th.

Slept Fifty Days.—A case of somnolence occurred in England within the past year, in which the patient, a young naval officer, slept for more than fifty days. During the year preceding his long sleep his time had been spent in severe study and he had not allowed himself the proper amount of sleep. His year's work culminated in a severe competitive examination for position in the navy, in which examination he was one of the fifteen successful applicants. About a week after his examination he began to grow drowsy, and promptly went to sleep from which he could with difficulty be aroused. A couple of days later he sank into a calm, peaceful sleep, from which it was impossible to arouse him completely, and when aroused partially he would drop off again almost immediately into deep slumber. No evidence of uremia was discoverable, nor anything suggestive of catalepsy. His color was good during the entire period, his extremities warm, temperature normal, tongue thickly coated with light brown fur, and the pulse slow and feeble. There was no anesthesia or suggestion of headache. The knee-jerk was exaggerated, particularly on the left side, and ankle-clonus was sometimes present. The sleep was at no time "profound." Toward the end of his sleep he could be more easily aroused, took more nourishment, and began to gain in weight. When he awoke he had perfect recollection of all the events that had transpired up to the day he went to sleep, but none of anything that had been done to him during his sleep. He had to learn again how to walk and how to balance himself. He regained his coordination rather slowly, and at the end of four months after his awaking had not completely regained his ability to walk naturally. Two months later he had so far recovered as to attend to his duties on board ship.—*British Medical Journal.*

CORRESPONDENCE.

MEDICAL MATTERS IN CHICAGO.

[From a Special Correspondent.]

DRY-AIR TREATMENT OF TUBERCULOSIS—OFFICERS OF THE CHICAGO GYNECOLOGICAL SOCIETY—ACUTE CEREBRAL MENINGITIS—INFLATION OF BILIARY PASSAGES TO DETECT SITE OF STONE—TREATMENT OF TYPHOID FEVER—THE VALUE OF WIDAL'S TEST.

CHICAGO, October 31, 1898.

THE Murphy plan of treating pauper patients afflicted with tuberculosis of the lungs is to be given a trial at the new Charity Hospital which will be opened for the reception of patients at Dunning on November 1st. This institution is designed to put in practice the dry-air treatment for consumption, and will accommodate 450 patients. The object is to reproduce, as nearly as possible, the climate of Arizona and New Mexico. The County Board of Commissioners appropriated $60,000 for this hospital, and more recently $3000 more has been set aside to complete the work. Statistics show that $\frac{1}{11}$ of the deaths in Chicago are caused by consumption, and that $\frac{1}{8}$ of all of the deaths in the civilized world are due to the same disease. Among those who die between the ages of twelve and sixty years the cause in one-fourth of the cases is tuberculosis.

At the annual dinner of the Chicago Gynecological Society, recently held, the following officers were elected for the ensuing year: President, Dr. Nicholas Senn; vice-presidents, Drs. Thomas J. Watkins and Reuben Peterson; secretary, Dr. William H. Rumpf; treasurer, Dr. Addison H. Foster; editor, Dr. Charles S. Bacon.

Dr. Daniel R. Brower read a paper before the Chicago Medical Society recently on acute cerebral meningitis, in which he reported forty-six cases occurring in his own practice and that of others, with thirty-three recoveries and thirteen deaths. In the treatment a dark, well-ventilated, quiet room is selected. The patient's head is shaved and surrounded by ice-bags; leeches are applied over the temples; the pain is mitigated by morphin or antipyrin hypodermically; the temperature is reduced by cold sponging; the bowels are freely moved by calomel, and every day there is applied freely to the scalp a ten-per-cent. ointment of iodoform in lanolin. The difficulty of administering medicines by the mouth in these cases led him to adopt the treatment by inunction about fifteen years ago, first with mercury, without success, and then with iodoform, with some success. Absorption usually takes place promptly, so much so that he has been able to detect the iodin in the urine and saliva one hour after inunction. The amount absorbed cannot be very great, inasmuch as he has never seen the untoward effects that sometimes follow the use of iodoform in open wounds, although he has used as much as 10 grams (154 grains) of the drug in one case. He has suggested this treatment in consultations in at least a hundred cases, but has been able to learn of the results of treatment in forty-six cases only.

At a subsequent meeting of the Society, Dr. Weller Van Hook spoke of inflation of the biliary passages in operations for cholelithiasis. In a case of choledocholithiasis he had injected air into the biliary passages to demonstrate the site of the stone in relation to the other ducts and to enable him to pass metallic sounds upward and downward along the ducts. The air was injected by means of a small bicycle pump, which was attached to a rubber tube fastened into the gall-bladder by means of a metallic tip. The method may be applied to any operation upon the biliary passages, enabling one to determine the location, size, and relations of these passages; to map out the position and relations of a stone, and to demonstrate fistulæ and diverticula.

At a meeting of the Chicago Society of Internal Medicine, held October 19th, Dr. J. M. G. Carter presented a contribution on the treatment of typhoid fever, based upon a study of seventy cases. Before he began the treatment of these patients his observations had convinced him that the danger in typhoid fever lies in the pronounced exhaustion present in this disease. In an

attempt to find a scientific line of thought he has been guided by the knowledge first, that typhoid fever is a bacterial disease; second, that typhoid bacilli exist at all times and in nearly all places, but in varying numbers; third, that under certain conditions the number or activity of these bacilli, or perhaps both, may be increased; and, fourth, that the virulence of the disease depends upon the number or activity, or both, of bacilli in an individual case. A careful consideration of these facts led him to conclude that the treatment may be reduced to meeting three indications, only two of which are always of paramount importance: the maintenance of the patient's strength by proper nutrition and the removal of the cause and reduction of temperature. The determination of what diet is proper in a case of fever is of the utmost importance. The high temperature of the patient must be combatted with antipyretics. He has never used the Brand system of cold baths. Ordinarily he makes use of quinin or of some coal-tar derivative combined with a heart tonic, or tepid, cool, or cold water for bathing. Sometimes he combines the two methods. He gives aromatic sulphuric acid and tincture of digitalis combined throughout the entire course of the fever. He did not give salol, sulphocarbolate of zinc, salicylate of bismuth, or other antiseptic in his treatment of the first fifty-five patients, although he did administer aromatic sulphuric acid, and some of the severest forms of the disease he has treated were included in the group reported. Other remedies are given only as may be required to meet emergencies as they arise. A happy result of this treatment is a more rapid convalescence than is secured when over-feeding is not allowed, but the course of the disease is not abridged in many cases,

Dr. Adolph Gehrmann gave the results of Widal's test in the diagnosis of typhoid fever from dried blood-specimens. He gave an analysis of 340 examinations. His conclusions were: (1) that dried blood specimens give results sufficiently accurate for public-health purposes, contrary to the opinions of some writers; (2) it is the simplest means of obtaining and transporting material for examination; (3) the development of the method employed is of more importance than slight changes of technic, as regards accuracy of results; and (4) the test is not an early diagnostic sign, and is not generally conclusive before the end of the first week of the fever.

SOCIETY PROCEEDINGS.

NEW YORK STATE MEDICAL ASSOCIATION.

Fifteenth Annual Meeting, Held in Mott Memorial Hall, New York City, October 18, 19, and 20, 1898.

(Continued from page 576.)

THIRD DAY—MORNING SESSION.

The Secretary was instructed to cast the ballot of the Association for the following officers for the ensuing year: President, Joseph D. Bryant of New York County; vice-president, J. G. Hunt, First district; D. C. Moriarta, Second district; F. D. Reese, Third district; W. M. Bemus, Fourth district; secretary, M. C. O'Brien, New York City; treasurer, E. D. Ferguson, Troy. Council—Jno. P. Sherer, C. E. Fritts, L. J. Brooks, Delancey Rochester, Chas. E. Dennison.

The discussion of

INTESTINAL OBSTRUCTION

was continued by Dr. Frederick Holme Wiggin of New York in a paper on "The Technic of Operative Treatment of Intestinal Obstruction," a very complete paper, of which some of the practical points were as follows:

When volvulus occurs in the small intestine it is not only safe but desirable to draw the intestine out of the abdomen, taking care to keep it hot and moist by wrapping it in gauze or soft towels wrung out of hot saline solution. When an intussusception is the cause of the obstruction the tumor should be encircled below its apex by the finger and thumb and the sheath held a few inches lower down, while the apex of the tumor is pushed upward. Traction from above the tumor should not be employed. If the intussusception is irreducible, the following method, described by Maunsell, is recommended: A slit is made in the intussuscipiens and gentle traction is exerted on the intussusceptum until its neck appears outside the opening in the intussuscipiens. The base is then transfixed with two straight needles, armed with horsehair, and the intussusception is amputated one-fourth of an inch above the needle. The sutures are now passed through the invaginated bowel, caught up in the interior of the bowel, divided, and tied. The invagination is then reduced, and the slit closed. Thanks to modern surgery, most neoplasms causing intestinal obstruction can be removed, and naturally such a course is preferable to colotomy. Where it is inadvisable to resect the portion of bowel containing the growth, an incision, four inches long, should be made over this portion, in the direction of the fibers of the external oblique, and the bowel drawn upward until its mesenteric attachment is on a level with the external incision. A slit is then made in the mesentery and a glass rod is passed through, and iodoform gauze wound around the ends of the rod. The rod is left in position until adhesions have formed, when the gut is opened.

When the intestinal obstruction results from the pressure of a neoplasm external to the gut the new growth should be extirpated, but if this is not possible, a fecal fistula must be established above the point of obstruction. Gall-stones or enteroliths causing obstruction should be pushed a little upward or downward and then removed by an incision. The object of this is to avoid making the incision through the portion of the gut which is likely to have been damaged by pressure. When the gut is found to be gangrenous, in a case of intestinal obstruction, an end-to-end anastomosis should be done, and for this purpose Dr. Wiggin prefers his modification of Maunsell's method. The modification consists in doing away with the invagination and the slit. The portion of intestine to be extirpated is emptied of its contents by pressure. The portion to be removed is then isolated by clamps on either side, and a V-shaped incision is made, having its

apex in the mesentery. The mesenteric vessels are ligated before being cut, and the wound in the mesentery is sutured. After washing the divided ends of the bowel with hydrogen dioxid they are united by two sutures passing through all the intestinal coats, the first suture being at the inferior or mesenteric border, and the second directly opposite at the highest point. The third and fourth sutures are passed on either side half way between the first two. The other sutures are passed in the same way, the needle going from within the gut and piercing all the coats, then back through the peritoneal, muscular, and mucous coats to the interior of the other segment of bowel. The ends are then tied in the bowel. This process is continued until all the sutures but one or two are passed. For the latter, Lembert sutures are substituted. If the sutures have been properly inserted and tied, the peritoneum will now be turned in and the stitches hidden.

After the operation Dr. Wiggin thinks that the tendency is to give too little food and to give what little is allowed too frequently, so causing irritability of the stomach and loss of appetite. His rule is now even in intestinal cases to treat his surgical patients as medical ones, and if they are in good condition, with uncoated tongue, slight fever, and an appetite for food to let them have it in reasonable quantities. In his recent cases of end-to-end anastomosis he has put into the bowel just before inserting the final sutures of coaptation 2 or 3 ounces of saturated solution of sulphate of magnesia (McCosh's method) and has had excellent results. Patients present scarcely any disturbing symptoms on the days immediately after operation. In a very recent case, in which parts of the transverse colon and of the stomach were removed for malignant disease, the patient got along admirably with this expedient. Intravenous injection of normal salt solution quells the thirst and keeps the patient from being restless during the time it is not thought advisable to exhibit liquids.

DR. MARCEY of Boston, in the discussion of this paper, said that the hope for the improvement of the statistics of the surgical treatment of intestinal obstruction lies in early diagnosis and in improvement of the technic of intestinal anastomosis; neither the Senn's rings nor the Murphy button has solved the problem though it was hoped they would. Dr. Wiggin's method was certainly a step in advance. He himself employs a method that saves a good deal of time. He slits longitudinally each end of the bowel to be approximated so that it resembles the cuff or wristband of a shirt. This enables him to bring the ends together and unite them by a continuous suture along a straight line. There remains then to be closed only the longitudinal slits made in the ends of the bowel. This may be done by the Lembert suture. All abrasions of peritoneum and all roughness is covered in as such things inevitably lead to peritoneal adhesions as surgeons are learning by bitter experience at last.

DR. FARRINGTON of Boone County read a paper on

THE PASSING OF ALCOHOL

that led to some lively discussion on the subject of alcohol in medical practice.

DR. H. S. OPPENHEIMER of New York County read a paper on

EYE LESIONS IN SOME KIDNEY DISEASES.

The better prognosis of all eye lesions from kidney trouble that develops during pregnancy was dwelt upon. Even attachments of the retina in pregnant women not infrequently involute and readhesion takes place after labor. Amaurosis from acute nephritis during the infectious fevers also was dwelt upon. This toxic amblyopia sometimes with complete loss of vision develops suddenly and is most alarming to the patient. There are usually cerebral symptoms but nothing abnormal can be seen with the ophthalmoscope. Prognosis is usually good as regards short duration and ultimate vision.

DR. J. H. WOODWARD of New York County read a paper, entitled

SOME OBSERVATIONS OF GENERAL INTEREST REGARDING THE CAUSE AND MANAGEMENT OF CATARACT.

He insisted on the slowness and uncertainty with which senile cataract develops, and deprecated the telling of patients as soon as an incipient cataract is manifest that they have such a hindrance to vision that will gradually get worse and finally necessitate operation. He quoted from his case-book cases from every decade after thirty years of age, where cataracts had remained absolutely unchanged for from five to eight years. He thinks that constitutional treatment is of value in early stages in preventing rapid development.

AFTERNOON SESSION.

DR. WM. D. GRANGER of New York County read a paper on

INSANITY FOLLOWING SURGICAL OPERATIONS.

A number of such cases are to be found reported in the literature, but greater attention in giving details of the patient's previous life must be reported if the cases are to be of any value in a statistical sense. Predisposition is the all important factor. Heredity being the most active predisposer, certain critical periods, especially of the sexual life, as puberty and the climacteric, seem to be predisposing agents. It is not the gravity of the operation that is the most active factor, for a notable number of cases of insanity have developed after the extraction of a tooth. Eye operations furnish a good proportion too. Most mental aberrations follow operations upon the genital tract in females. Careful inquiry should be made beforehand as to whether the subjects for operations are predisposed by previous mental trouble or by heredity to such accidents.

DR. C. C. FREDERICK of Buffalo, in discussion, spoke of the difficulties of getting such details of patients' lives and heredity. Patients themselves are sensitive, and friends will often say nothing of the patient's neuropathic tendencies, so that the doctor finds out only after insanity has developed that the patient had been in an asylum before.

DR. FREDERICK then read a paper on

THE PREPARATION OF CATGUT.

Ligatures of silk and silkworm-gut are always liable to be infected and cause troublesome, even dangerous, sinuses. Now that catgut can be prepared so as to be absolutely sterile and yet retain its tensile strength, the use of silk is almost unjustifiable. He demonstrated spools of catgut prepared by the formaldehyd (3 per cent.) method, guaranteed to stand boiling well, whose strength was thoroughly tested by those present. This gut can be chromicized to any degree and so its absorption regulated. A feature of the method is that but one row of turns of gut is on each spool, so that all of it is equally exposed to the formalin, and the free ends are tied together across the spool to prevent shrivelling.

DR. THOMAS J. HILLIS of New York County read a paper, entitled

WHAT TO DO TO BE SAVED,

being the conclusion of the inquiry into the abuse of medical charity. It was listened to with a great deal of interest, tinged with an amusement that was plainly sympathetic. Some idea of the drift of the paper may be gathered from the following characteristic quotations from it:

"The authorities of the hospital of to-day have forgotten the real mission of that institution; that its place is only as a dispenser and vender of medical charity."

"The transformation of the hospital from a purveyor of charity to a colossal corporation controlling the medical market and freezing out the general practitioner, is typical of this age of trusts and monopolies."

"Since the good old days when the word 'Doctor' expressed any value in hospital parlance, changes have come with a vengeance; the hospital has divorced itself from the doctor except to make him the tool with which to accomplish its purpose—a stepping-stone to advance its interests."

"What is the motive of the surgeon in working for nothing for a gigantic business concern that could well afford to pay him for his services?"

"The situation as it is: The governor in the saddle and the volunteer corps, the visiting staff, sullen, and mutinous."

"The day the hospital reached its majority and set up a household of its own, it should have crowned its entrance into manhood by paying every man, in whatever capacity attached to the hospital, the market value of his services."

"The old notion that surgeons and physicians should work for nothing for rich corporations styling themselves hospitals and who wear the trade-mark, charity, to deceive the unwary, is about exploded."

"The handwriting on the wall is becoming apparent; the peril of the governor is growing more and more imminent."

DR. F. W. HIGGINS of Cortlandt County read a paper, entitled

SENILITY.

He insists on the distinction between senility and senescence, between the gradual expansion of Nature's forces that constitutes the "natural disease of all life," and that degeneration of the cellular elements of the organism, often precocious, usually brought on by abuses of which alcoholism is one of the most prominent. Senility does not constitute a contraindication of operations, but senescence does, no matter what the age of the patient determined from his years.

DR. THOS. F. REILLY of New York County read a paper on

THE TECHNIC AND USE OF SALINE INFUSIONS.

He demonstrated the funnel, tube, and cannula for intravenous injection and dwelt on its usefulness. The intravenous injection of a pint or more of warm normal salt solution now constitutes the best remedy for surgical shock, for exhaustive hemorrhage, for uremia (some blood being taken away if deemed advisable before the injection, this method being what the French call washing out the blood), for diabetic coma (the benefit reported from the injection of bicarbonate of soda being probably due to the salt solution); in all serious toxemias, whether digestive in origin, or septic, or due to the ingestion of some vegetable or mineral poison; in acute suppression of urine, and in all conditions of lowered blood-pressure, also in apparent deaths from electricity and the like.

After the discussion of Dr. Reilly's paper the Association adjourned.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON GENERAL MEDICINE.

Stated Meeting, Held Tuesday, October 18, 1898.

THE Chairman, DR. LOUIS FAUGERES BISHOP, read an address, entitled

THE EVOLUTION OF SCIENTIFIC MEDICINE.

He said in part:

The fact cannot longer be ignored that great changes have taken place in the economic relations between physicians and the public. It has long been apparent that as a means of earning a livelihood and of winning a desirable position in a community, the profession of medicine does not offer the inducements to us that it offered to our forefathers. It would seem that the work of the average man has become more definite and clearly defined. We have come to do, each of us, some particular branch of our art better than in former times. In other words, the physician and surgeon has become more of an artisan and less of an artist. The artist constructs from his imagination—he idealizes. The artisan performs a definite work from carefully drawn plans. Even in departments of medicine that it would seem impossible to render scientific, such as mental diseases, the classification has advanced and recorded experience been accumulated until even the alienist can work according to rule.

But the evolution of the profession has also been affected by forces from without. The relation of the physician to the community has been profoundly modified by the general progress of knowledge and the extension of science and learning to so many fields of hu-

man activity. The number of professions in the true sense of the word has been enormously extended. The management of special commercial enterprises, such as railroads, electric systems, great financial corporations, and manufacturing companies, is no longer entrusted to chance employees, who have acquired skill merely through experience, but is conducted by persons especially trained in engineering and technical science. Professional training has become so diversified that the physician finds himself only one of a great many who are set apart to do a particular work because of special education. In the beginning the trades and business were far removed from science and the systematic improvement which comes through development along the lines of exact observation and inductive reasoning. Medicine also was involved in superstition and supported by authority rather than reason. As time has gone on the conduct of all human affairs—commercial, social, and even religious, has come under the dominion of the scientific tendency of the age which leads to simplification of method and organization of effort. At the same time medicine has thrown off mysticism, secresy, and reliance upon authority. So the public at large and physicians as a class have come near together, and the physician finds himself one of the large number of specialists and subservient to much the same laws as the others. As a laborer, he must find a market like his friends, the electric engineer and the rest, and must be governed by the same laws of fitness, supply and demand. Pressure of circumstances will compel him more and more to conduct the business side of his work in conformity with scientific business methods. In fact, to be unbusiness-like is to controvert the order of the just relations of man to man. Business in its best development is more highly moral than many a system of theology.

A great disturbing element in the business relations of physicians is philanthropy. The physician has more opportunities than others to exercise this faculty, and he also must be acknowledged as having more chances as an individual for gain by the wrongful exercise of the privilege of gratuitous service. He benefits himself but injures the business possibilities of other members of his profession. The same selfish principle is seen in the commercial world when large department stores sell without profit a class of merchandise which they do not care to handle except to induce crowds to come to their bazaar but which represents the means of livelihood of a large number of small shopkeepers. In this way, for the sake of prestige and experience, the older physician may injure the younger man, as witness the hospital and dispensary abuse. But fortunately philanthropy has not escaped the modern scientific fact that charity must be controlled by fixed principles and not left solely to the impulse of the emotions. Organization cannot long be deferred. Philanthropy is seeking more aud more the guidance of principles and facts developed by scientific method in observation and experiment.

The tendency in America is to give up all sects in medicine and allow physicians to choose their professional associates purely on the ground of integrity and personal preference. This liberal and scientific spirit has found its chief growth in New York State with the result that the controversial side of medicine has been abandoned for the scientific. New York may well be regarded as the center of influence of a modern school of scientific medicine, and a monument has already been raised to it in the amount of good work in investigation and analysis which has been done. The modern school of scientific medicine relies for its recognition and support upon a public educated in modern philosophy, a public dominated by the scientific spirit of a scientific age. It claims as an advantage that medical knowledge should be open to any curious seeker and that many medical facts should be of the common knowledge of the people. The public has already acquired that little knowledge which is so dangerous. It will not give it up. Our only salvation is to go boldly forward and educate the masses to a point where they themselves can discriminate between knowledge and imposition. The enemies of medicine have already entered upon a flank movement and the newspapers are blackened with advertisements of serums, extracts of organs and germ-killers, some of which assume the names of great discoverers. This movement of charlatanism was only to be expected and must be met by training the people to distinguish between science and fraud.

DR. R. H. CHITTENDEN, Professor of Physiological Chemistry in Columbia University, then read a paper on

THE RELATION OF CHEMISTRY TO PRACTICAL MEDICINE, AND SOME OF THE METHODS AVAILABLE IN THE DAILY WORK OF PHYSICIANS.

Physiological chemistry began to occupy a proper place in the scheme of medical studies only when the first independent laboratory was established in the Strassburg University twenty years ago. Since then every new fact which the laboratory has brought to light has added something to the fund of knowledge which is of practical value to the general practitioner, and the advance in the application of chemistry, physiology, and pathology has been so great as to warrant the expectation that further progress in scientific medicine will be along chemical lines in future. It has been shown that micro-organisms are not directly responsible for the ills which they produce, and that the characteristic symptoms are but the outward manifestations of the physiological action of the specific substance produced by the growth and multiplication of these organisms within the tissues of the body. It is now known that the Loeffler bacillus produces a soluble poisonous substance of a proteid nature which, when injected, will produce the characteristic symptoms of diphtheria and death. The production of an antitoxin which owes its antidotal action to chemical substances has been made possible by combined chemical and physiological study. According to Ehrlich the diphtheria toxin is a single definite compound with definite physiological and antitoxic properties as its origin only; it is instable, and the neutralizing power of a fatal dose varies greatly in different toxins. The latter readily deteriorate. Chemistry has shown that the growth of both pathogenic and non-pathogenic micro-organisms is accompanied by the devel-

opment of proteolytic enzymes, which are responsible for the soluble proteid products which result. The most prominent of these are albumoses or proteoses, and resemble those formed by the proteolytic enzymes of the digestive juices, which are toxic when introduced into the circulation. The soluble products of digestion when introduced into the blood-current are rapidly eliminated through the kidneys as are other poisons. In the decomposition of proteids by ordinary digestive fluid, enzyme, there takes place a progressive hydrolytic cleavage in which the first formed products (primary proteoses) become secondary products (secondary proteoses), and finally are transformed into true peptones. As a rule, the primary are much more active than the secondary products. The same thing occurs in the zymolysis, produced by many pathogenic micro-organisms. A corresponding hydrolytic cleavage results with the formation of a more or less toxic substance, one formed from the other by successive hydration, and accompanied by changes in toxicity or physiological power. All pathogenic bacteria produce a row of chemical substances possessed of more or less toxicity, to which are due the characteristic symptoms of the disease.

One can no longer doubt the existence of a row of chemical substances elaborated by the various ductless glands, such as the thyroid, which exert a controlling influence over the nutritional processes of the body, preventing the formation or counteracting the effect of powerful toxic substances. There is evidence to prove that chemical substances of undoubted physiological power are contained in the internal secretion of the thyroid, suprarenals, hypophysis cerebri, ovaries, testicles, etc.

The practical value to the physician of the chemical study of food, urine, and feces, as bearing upon the general problem of nutrition, cannot be overestimated. Quantitative analysis, in order to ascertain the true nutritive value of food and the extent of metabolism, will prove of inestimable value, and afford a basis for accurate diagnosis in questionable cases. It is to be hoped that the time will come when the same amount of thought as that given to the prescribing of medicines will be devoted to determining the exact nature and composition of food. Kjeldahl's method is simple and accurate in determining the nutritive value of the proteid and albuminous foods by detecting the amount of nitrogen present.

It is interesting to note the different forms in which nitrogen is eliminated in the urine, and much may be learned in this way. The quantitative method of Hopkins will determine sufficiently for clinical purposes the amount of uric acid excreted.

It is now known that uric acid has an origin quite apart from urea. Kossel has shown that true nuclein yields on decomposition a row of xanthin bases which contain an alloxin group and an urea group, and uric acid is an alloxin body. Foods which contain nuclein increase markedly the output of uric acid, and the continued excretion of uric acid during prolonged periods of fasting is largely due to katabolism of the nuclein-holding cells of the organism. The great increase in the excretion of uric acid in leucemia is undoubtedly due to the destruction of leucocytes which are rich in nuclein.

In determining the presence of urea with sodium hypobromite, it should be borne in mind that the latter decomposes other nitrogenous constituents as well as urea.

Of creatinin but little is known except that it increases under a meat diet.

Both leucin and tyrosin are pathological constituents of urine, and are the normal products of pancreatic digestion. They appear in the urine whenever the functional activity of the liver cells is interfered with, but are not pathognomonic of acute yellow atrophy of the liver as has been supposed. These substances should be sought for in the urine in cases of jaundice.

The presence of melanin does not necessarily point to the existence of a melanotic tumor.

Originally it was thought that the diazo-reaction of Ehrlich was pathognomonic of typhoid fever, and Ehrlich believes it to be of clinical value, but it has been shown that chemogen, the cause of the reaction, is found in other febrile diseases, and particularly in pulmonary tuberculosis.

Indican, which ranks first among the normal chemogens of the urine, is the product of oxidation of the indol formed in intestinal putrefaction. Micro-organisms in the intestinal tract are alone responsible for the formation of indol and its subsequent appearance as indican in the urine. Consequently the amount of indican found in the urine will indicate the extent of intestinal putrefaction. Indican is also present in the urine in nearly all cases in which there is hyperacidity of the gastric juice.

The presence of acetone and diacetic-acid in the urine is of special significance to the physician, for they owe their origin to the breaking down of the proteid matter of the tissues, and are, therefore, conspicuous in cases in which inanition is marked.

In testing for sugar the Bottger-Allmen-Nylander test should be employed in addition to the Fehling-test. The phenylhydrazin test is absolutely reliable and unerring.

The tests usually employed to detect albumin in the urine merely indicate the presence of albuminous matter without reference to the character of the proteid. Careful examination should determine this.

Ewald's test meal in gastric indigestion furnishes another example of the intimate relation between chemistry and practical medicine, the determination of total acidity, the relative proportion of free and combined hydrochloric acid, and the presence of lactic or other organic salts, now being made by various chemical tests.

Physiological and pathological chemistry are closely allied to physiology and pathology. The normal must be fully understood in order that the significance of the abnormal may be appreciated, for the dividing line is exceedingly thin and wavy. Many of the deviations from the normal which are the forerunners of disease, may be made clear by chemistry. It is to be hoped that the intimate relation which chemistry bears to scientific medicine may be more fully appreciated, and that the use of the many practical methods which chemistry offers as an aid to diagnosis may become more and more extended.

DISCUSSION.

DR. BEVERLY ROBINSON: Much as I desire to express some views upon the subject of the relation of chemistry to practical medicine, I think it would be wise for me to decline to do so because I am not a chemist. I know very little about the chemistry of to-day, and I am not ashamed to say so for I believe the same is true of pretty nearly every practitioner of medicine. Fortunately for us, there are a few exceptions—men who have been able to combine with the art of medicine a great deal of scientific attainment. I do not claim to be such. I would like, however, to make some remarks in regard to why the practitioner knows little or nothing of chemistry. At the College of Physicians and Surgeons it is not necessary that a man know chemistry before beginning the study of medicine; therefore, unless he has been fortunate enough to have some preliminary training, he must get the best chemical knowledge he can during the first or second year of his college life. Now, the time is short and there are other things to learn besides chemistry, and it is pretty hard work. A man has no time for amusement and but little time for the exercise upon which his health depends. No one will deny that it is important to have a wide chemical knowledge, but the fact remains that it is impossible to do more than a certain amount of work during a certain number of hours. It would be wise for colleges to insist upon men receiving a preliminary training in physiological and pathological chemistry before beginning the study of medicine. So much for the colleges. Now for the hospitals.

I for one acknowledge that I, to-day, have to learn much from younger men—the hospital interne. I have a great respect for these young men, for they know a great many things which I do not know. I believe these young men should have the opportunity of perfecting themselves in bacteriology and physiological and pathological chemistry. I would have endowed laboratories in every hospital in the country with a competent man at the head of each. I certainly think that scientific research should be encouraged, and this can best be accomplished by the endowment of laboratories. I want it distinctly understood, however, that I, as a practitioner of medicine, do not propose now or in the future to allow any chemist or bacteriologist, never mind how wise, to tell me that he is to control the situation. I believe and always have believed that clinical medicine above everything should control all along the line. Let the chemists and bacteriologists bring their acquired facts to those of us who have made a life-work of the study of disease—it is for us to hold the fort. These men should not think that their varying science—for it is varying—can make up for years of clinical experience. And yet I do not want you to believe that I do not fully appreciate the immense advantages which have been gained by scientific research. I realize all that we owe to bacteriology and to chemistry.

DR. W. H. THOMPSON: When I was asked to come here to-night and take part in this discussion, I was at a loss to know what I was expected to talk about because of the fact that the subject practically covers the whole field of medicine to an extent which only those who pay attention to the great problems of medicine can appreciate. Take for instance the question of infection. It was a great step when chemistry discovered that this was not due to direct contagion. Then we heard of bacteria and plasmodia, and this explained the period of incubation and the development of infection by a series of time-limited processes. It also solved the still greater problem as to how these processes resulted in the proliferation of the infecting agents. It explained why different persons exposed to the same infection did not all fall a prey to it, because of the different nature of the soil on which the seed fell, and, finally, it explained that the disastrous effects which they produce are due to the products which they form. The practical physician wishes to know all he can about these subjects.

The author has discussed the methods of discovering certain ingredients of the urine, but can he promise us that chemistry will soon be able to come to our aid in answering the exceedingly puzzling questions in connection with uremia? I have failed to get a single hint from him on this subject. I know of nothing more difficult to understand than the kidney. One can remove two-thirds of both kidneys and they will secrete more urine and urea than before. If three-fourths of both organs are removed there is still an increase in the amount of urine and urea excreted, but this will be followed by emaciation and death. How can this be explained. Would you say that dropsy is due to a disorganization of the kidneys in a patient who has been passing a great deal of urine? How do you explain those cases in which the kidneys are not able to send a drop of urine to the bladder on account of, say, impaction? You will find it difficult when called into consultation to explain to the attending physician that the patient is sure to die, but will die without any symptoms or uremia—no vomiting, no convulsions, and with no albumin in the urine. Such patients die of asthenia as do animals who have had their ureters tied off. Chemistry has not yet given us an explanation for this.

Again, what is the significance of pale urine? It is easy to say that it is a sign of a nervous, hysterical condition. Others say that it is a pronounced sign of structural changes in the kidney. I always regard pale urine as a serious symptom in diabetes.

In regard to auto-infection, my experience has taught me to look upon intermittency as a sign of auto-infection. An epileptic or a person who suffers from periodical attacks of migraine might be brought before the best neurologists in the land, and they would not know that the first was an epileptic, unless he fell at their feet in a fit, or that the second was periodically prostrated by the most intense headaches. These intermittent nervous affections, which are characterized by absolutely no sign of their presence during the intervals between the attacks, are fundamentally different from affections due to structural changes. These nervous explosions, convulsions, attacks of asthma, migraine, etc., are explained by poison—auto-infection. I am satisfied that a further elucidation of this subject is to be found in the direction of chemistry. We cannot lay too much importance upon

chemical examination of the urine and contents of the stomach and intestines. I hope we will all take to heart what Professor Chittenden has been telling us about the gastric reactions. These are of especial value in typhoid fever.

I am gratified to hear Professor Chittenden lay emphasis upon the presence of indican in urine. A friend of mine has discovered that the administration of ether has a most disastrous effect upon the kidneys, very different from that which follows the administration of chloroform. Perhaps the presence of indican in the urine has something to do with this. In any case it should be recognized as a signal of danger.

DR. MORRIS MANGES: I regret that I did not hear the paper, but from what has been said in the discussion I infer that the relation of chemistry to diseases of the stomach has been referred to by the author. There is no organ more indebted to chemistry than the stomach. The analin dyes began to be used for testing the gastric juice less than twenty years ago. The reason why the general practitioner pays so little attention to intestinal chemistry is because he thinks the subject too complicated for him. In reality it is very simple, and the various tests can be carried out by anybody. Nothing is easier than the analysis of the contents of the stomach. A specialty should not be made of diseases of the stomach which belong to the field of the general practitioner as much as do diseases of the lungs, heart, and liver. If the schools would devote to the study of physiological chemistry one-half the time they give to the routine study of anatomy, and if students were compelled to study test-tube reactions instead of tracing the course of nerves and arteries—which are at once forgotten and can always be referred to in the books—physicians would be better able to practise medicine.

DR. ACHILLES ROSE: It seems to me that it would also be well to study the chemistry of respiration. As you all know, tuberculosis has been treated by inflation of the rectum with carbonic-acid gas, and it has been found that although a cure could not be effected, many of the symptoms were relieved by this treatment. No effect was produced upon the bacillus, but the patients coughed less, had less fever, and the general condition improved. This result is explained by chemistry. When the rectum is inflated with carbonic-acid gas the latter is introduced into the venous system, and is eliminated by the lungs. According to the law of diffusion the more carbonic-acid gas eliminated the more oxygen descends. This exchange of gas takes place in the alimentary canal, with the result that the tissues are enriched with oxygen. I have recently employed with good effect inflation of the rectum in a girl of sixteen suffering from chorea. Many things of therapeutic value may be learned from a study of the chemistry of respiration.

REVIEWS.

DISEASES OF WOMEN: A MANUAL OF GYNECOLOGY. By FRANCIS H. DAVENPORT, M.D., Assistant Professor of Gynecology in the Medical Department of Harvard University, Boston. New (third) revised and enlarged edition. Philadelphia and New York: Lea Brothers & Co., 1898.

IN this enlarged edition of his popular book, Dr. Davenport has embodied the medical treatment of gynecological diseases as well as the surgical. The size of the volume precludes the possibility of pathological discussions and of descriptions of rare diseases, but, as heretofore, the work stands as one of the best, and by this we mean most lucid and scientific of the manuals which treat of the diseases of women. As a working-book for the student or the general practitioner there is none better. The book is profusely illustrated and handsomely printed.

A TEXT-BOOK OF PRACTICAL THERAPEUTICS, with Especial Reference to the Application of Remedial Measures to Disease and Their Employment upon a Rational Basis. By HOBART A. HARE, M.D., B.Sc., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Seventh edition. Philadelphia and New York: Lea Brothers & Co., 1898.

THE necessity, within a year, of issuing a new edition of this work, now in its eighth year of life, is sufficient evidence of its worth and its popularity. As heretofore, the first part of the book deals with drugs and their therapeutic applications, as well as with therapeutic measures of other kinds, including baths, enemata, feeding, infusions, mineral springs, and climate. The second half of the book is devoted to a consideration of diseases, with a discussion of the drugs suitable for and indicated in the various ailments and their complications.

In the present edition the author has brought the book thoroughly up to date, and has made the preparations of drugs conformable to the British Pharmacopœia as well as to that of the United States. We can, therefore, assume that his work will soon meet a popularity on British soil second only to that which it enjoys in this country. A number of new illustrations have been added. We shall not be surprised to see at an early date an eighth edition of this deservedly popular book.

OUTLINE OF PRACTICAL HYGIENE. By C. GILMAN CURRIER, M.D. Third edition. New York: E. B. Treat & Co., 1898.

THE book before us treats of a subject which evidently has been considerably neglected in several quarters if what we hear in regard to the selection and the health of military camps be true. A few words, such as found upon page 40, if acted upon would have saved many lives. The author here states in the chapter on soil and climate: "If camping out, the site should be dry, and not have water near the surface. . . . . Moist river bottoms and valleys are not to be chosen for camping-grounds." And further, on page 41, "Wherever one goes, it is important to see that the *water-supply* is very free from chances of contamination." There are many points contained in this work as important as those cited above which would be of benefit to health-officers and persons at the head of sanitary departments.

The chapters on heating and ventilation are of particular interest in view of the approach of winter, the season in which our homes are more or less in an unhealthy state owing to the erroneous methods employed.

Dr. Currier has incorporated in his book all of the most important points to be considered in public hygiene, and its perusal might be recommended to the medical profession as well as to the general public. A complete index completes the work.

A CLINICAL TEXT-BOOK OF MEDICAL DIAGNOSIS FOR PHYSICIANS AND STUDENTS. By OSCAR VIERORDT, M.D., Professor of Medicine at the University of Heidelberg. Authorized Translation by FRANCIS H. STUART, A.M., M.D. Fourth American, from the fifth German, edition. Philadelphia: W. B. Saunders, 1898.

AN extended notice of the fourth edition of this widely known book on medical diagnosis is scarcely called for. The pioneer in works of this character, Professor Vierordt's book has long held its own, and, during the ten years which have elapsed since it was first published, it has become a favorite with teachers and students as well as with the great bulk of the medical profession. It is a perfect storehouse of information on clinical and laboratory methods of examination and in this edition has been brought thoroughly up to the latest accepted teachings. We note especially that the chapters dealing with the examination of gastric contents, the nervous system, and the microscopic examination of the blood have been revised and enlarged. The translation has been admirably made, retaining the force and virility of the original without a sacrifice of clearness. The typographic appearance of the book leaves nothing to be desired.

A TEXT-BOOK OF MATERIA MEDICA, THERAPEUTICS, AND PHARMACOLOGY. By GEORGE FRANK BUTLER, Ph.G., M.D., Professor of Materia Medica and Clinical Medicine in the College of Physicians and Surgeons, Chicago. Second revised edition. Philadelphia: W. B. Saunders, 1898.

THE wisdom of the publisher is sometimes greater than that of the critic. We did not believe when this book passed through our hands two years ago that it would grow into a lusty youngster; we were inclined to think that its faults so overbalanced its virtues that it was not long for this life. But it seems we were prognostically wrong. The second edition, somewhat amended, lies before us. The author still uses the almost homeopathic phrases, "disease medicines" and "symptom medicines," whatever these may be, the same delusive illustrations are found scattered through the text and the same hazardous statements are here and there met.

But the book has much in it that is good. Especially is this true of the chapter on serum-treatment. Most of the text is in harmony with accepted teaching and as a text-book for the student it is safe. The make-up of the book is handsome, indeed. But we wish we could assist in revising the text when a third edition, which we hope may be necessary, shall appear.

A GUIDE TO THE CLINICAL EXAMINATION OF THE BLOOD. By RICHARD C. CABOT, M.D. Third revised edition. New York: William Wood & Co., 1898.

DR. CABOT'S book must have hit the mark, for within two years a third edition has been demanded. We said when referring to the first edition, "it is a well-conceived, well-written, almost complete, hand-book," and we have nothing to retract. It is better now than it was two years ago for it contains most of what is new, and all that is good, of the discoveries in this branch of clinical medicine since the first edition was written. There are descriptions of Fliner's tintometer and hemoglobinometer, a description of Müller's blood-dust, the test by anilin colors of diabetic blood and blood examinations in some of the infectious diseases. We regret to find that the author still insists on holding the cover-glass with his fingers instead of with forceps; yet this is a mere detail.

The book is one of those one can heartily commend to every one who wishes to study the blood in a scientific spirit. It is a thoroughly scientific, thoroughly modern work on an important subject.

THERAPEUTIC HINTS.

For Diabetes Insipidus in Children.—The following prescriptions are recommended by MONTI.

1. ℞ Quininæ sulphat. . . . gr. xx
   Zinci sulphat. . . . gr. v
   Sacchari . . . . ʒ iiss.
   M. Div. in chart. No. XXX. Sig. Five powders daily.

2. ℞ Liq. potassii arsenitis } aa . . ʒ i.
   Tinct. valerianæ }
   M. Sig. Five to ten drops three times a day.

3. ℞ Chloralis hydrat. . . gr. xvi–xxvii
   Syr. acaciæ . . . ℥ iv.
   M. Sig. Three or four tablespoonfuls a day.

The diet should be restricted to vegetables and milk or milk alone. Sweetened or salted foods should be avoided. Hot baths, moderate exercise, and mineral purgative waters when indicated are further noted for the course of treatment.

For Infantile Chorea.—

℞ Acidi arseniosi . . . . gr. iss
Aq. dest. . . . . ℥ iii.
M. Sig. From one-half teaspoonful to seven teaspoonfuls a day.

According to FILATON this is better tolerated than Fowler's solution or the arsenate of soda. Begin with ½ teaspoonful for a child of four to ten years, or 1 teaspoonful if over ten years, augment the daily dose during the first week, diminish it during the second, and so on. The maximum daily dose for the younger child is 3½ teaspoonfuls, for the older, double this quantity. If not borne by the stomach Filaton advises the use of Fowler's solution hypodermically in doses of $\frac{1}{24}$ to $\frac{1}{12}$ of a grain.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIII. NEW YORK, SATURDAY, NOVEMBER 12, 1898. NO. 20.

ORIGINAL ARTICLES.

A NEW URINARY DISINFECTANT.

BY REYNOLD W. WILCOX, M.D., LL.D.,
OF NEW YORK;
PROFESSOR OF MEDICINE AND THERAPEUTICS AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND ATTENDING PHYSICIAN TO THE HOSPITAL; VISITING PHYSICIAN TO ST. MARK'S HOSPITAL.

THE problem of how to disinfect the urine has long been a subject of careful study. Many substances lauded in the text-books are disappointing when put to the test either in the cystitis of prostatic hypertrophy or in that of vesical fistula. The latter is the *bête noire* of the surgical wards until such time as the site is in readiness for operation. In the first instance, indeed, while operative procedures (castration, cystotomy) give a fair measure of success, not all are curable by them nor indeed are surgical palliative measures (irrigation, catheterization at regular intervals) entirely free from danger. There is, then, a very large proportion of these sufferers who should not be subjected to local treatment, either because they die if it is attempted, or it is attended by sufficient risk to contraindicate it. To render an acid urine alkaline is not a matter of much difficulty for all salts of the metals potassium, sodium, lithium, and calcium will do this; even the tartrates, citrates, and acetates—for they are eliminated as carbonates, but to a less extent. Even nitric acid, through its conversion into ammonia, may do this. The only question is that of dose and what particular salt the stomach of the patient will tolerate. Litmus paper informs us when the result is accomplished. The generally received opinion is that an excessively acid urine is irritating. While this in a measure is true, it is also a fact that an alkaline urine can be irritating also. Reaction then, considered as such, does not entirely determine the bland or irritating properties of the urine.

In rendering an acid urine alkaline two distinct propositions are involved: (1) Drugs which of themselves alter the reaction, and (2) those which inhibit or prevent its decomposition. The latter need not be dependent upon the former. Of drugs which prevent the urine from decomposing may be mentioned the benzoates, the salicylates, those containing arbutin, as uva ursi and chimaphila, and certain drugs containing volatile oils as copaiba, cubeb, sandal wood, and others. Arbutin, by its decomposition in the kidneys, breaking up into glucose and hydroquinone is fairly efficient, yet it is generally believed that administered as such it is useless. Hydroquinone is undoubtedly set free in the kidneys, else poisoning would take place more frequently. The volatile oils, often of value, are likely to disorder the stomach and some substances containing them, as copaiba, give rise to disagreeable exanthemata. The free use of the salicylates presupposes the fact that the integrity of the kidneys is established; of the benzoates, mention will be made later. When it is remembered that all of these urinary antiseptics are generally administered in conjunction with urinary sedatives, as some of the *solanaceæ*,—belladonna, hyoscyamus,—it is clear that full reliance is not placed upon their antiseptic action.

Of drugs which render an alkaline urine acid, hitherto the benzoates have held first place, the influence of salicylic acid being slight in comparison. It is also true that large doses of citric and tartaric acid, of citrates and tartrates, have a similar effect. At another place I have said that saccharin will possibly render an alkaline urine acid. This is undoubtedly true, but only so far as saccharin exerts its antiseptic properties during its elimination, as unchanged saccharin, by the urine. The use of large quantities of water containing carbon dioxid, as first advocated by Ultzmann, has not given uniformly or markedly good results.

In dealing with irritating alkaline urine or with urine depositing phosphates, a urinary acidifier is desirable. In treating patients upon whom local measures, when carried out, result in disaster such a remedy is required. If it shall be proven that a remedy possessing such properties is also a safe and effective urinary antiseptic a real addition to our resources has been made, and when Nicolaier nearly four years ago offered hexamethylentetramin as a remedy which would accomplish both results—clear up a decomposing, and acidify an alkaline urine—the matter seemed well worth investigation. This substance is prepared by union of ammonia and formaldehyd in solution and occurs as colorless crystals which are readily soluble in water and possess the formula $(C_2H)_6N_4$. On account of the various ways in which this substance alters urine it has been named urotropin (from οὖρον, urine, and τρεπω, to change). Its first use was as a diuretic and lithon-

triptic. For the latter purpose its ready combination with salicylic acid gives it a peculiar value. That on internal administration it is readily eliminated by the kidneys is shown by its detection with bromin-water (precipitate of urotropin bromid) even within fifteen minutes. Were the good results from its use due only to dilution of the urine from its diuretic effect but minor claims would be made for its efficiency. It is a well-known fact that even uric-acid calculi may be disintegrated by prolonged immersion in a water which is effective in proportion to its purity. To this physical fact certain waters owe their reputation, rather than to the name which they have, or the substances which they are supposed to contain. Thus we must look to a direct action of the drug itself rather than to its diuretic properties however useful these may be. That when excreted in the urine this remedy dissolves uric-acid calculi there is positive demonstration. As for its antiseptic properties Nicolaier's early experiments showed that urine in which was excreted urotropin remained sterile after inoculation with pure cultures of the *bacterium coli commune* and that the drug hinders the development of micro-organisms such as the bacteria of ammoniacal decomposition. He also calls attention to the fact that the *bacterium coli commune* may frequently be a factor in many bacterial diseases of the urinary passages.

As to the mode of action and history of this remedy in the organism Casper has made some observations which tend to show that some of it in the organism is decomposed into formaldehyd. Urotropin was always detected in the urine and sometimes in the blood; formaldehyd sometimes in the blood and generally in the urine, the reason of these variations probably being because there is a combination of this latter substance with albuminous substances in blood or urine so that its presence cannot always be determined. Both substances have been found in the urine as early as ten minutes after administration and as late as fourteen days; generally the period of elimination is much shorter. So much has been written upon the antiseptic properties of formaldehyd, so much laboratory work has been done and its use has been so extensive in practical disinfection that it is superfluous to recapitulate what is already definitely known and what has been put to practical use.

The final question now arises, Is urotropin an absolutely safe remedy? This is of especial pertinence for sound kidneys are the exception when a patient has suffered from long-standing cystitis, no matter what the original cause may have been. The kidneys are subject for suspicion when disorders of metabolism, of which uricacidemia is one expression, have been marked. It is perfectly true that large doses (90 grains *per diem*) have given rise to burning in the bladder region, urethral pain, and increased desire to micturate. If, when these symptoms have arisen, the same dose is maintained, occasional blood-corpuscles and some transitional epithelium may appear in the sediment. All these symptoms promptly disappear as soon as the dose is diminished. Thirty grains per day are sufficient and from this amount no untoward symptoms have been encountered nor do I know of any record in extant literature. That the decomposition of urotropin into formaldehyd takes place in the blood is evident from the observations of Linossier, who shows that this substance even in well-diluted solutions is a gastric irritant.

The following instances of the use of this remedy are typical ones:

Case I.—In December, 1894, a gentleman of sixty years of age was seen at his residence. For the preceding four months he had been unable to lie down because of a distressing shortness of breath and incessant cough. Physical examination revealed ascites, hydrothorax, pulmonary edema, aortic and mitral incompetency with dilatation of the left ventricle. Under appropriate treatment the various collections of dropsical fluid were gotten rid of, the heart compensated, and March, 1895, found him able to sleep in bed six to eight hours at night, and in a fairly comfortable condition. He has been under observation during the time which has elapsed until April, 1897. At that time he began to rise more frequently at night, there were frequent stoppages of urine and the voiding of it caused pain. Physical examination showed that cardiac compensation had been maintained and his general condition was fairly satisfactory, slight edema of the feet being excepted. The prostate was found to be distinctly enlarged and there was marked tenderness on pressure over the lower ribs on both sides. The following is the report of the examination of urine: April 9 and 10, 1897, quantity 63 ounces (24 urinations); specific gravity, 1018; reaction when examined, strongly alkaline; odor, ammoniacal; sediment, large amount, ropy. Chemical analysis: Albumin present, ¾ of 1 per cent. by weight; indican, increased; blood, absent; urea, normal; uric acid, diminished. Microscopical examination: Casts, few hyaline and finely granular; pus, present in large amount; epithelium, large amount of pelvic and bladder; crystals, ammonio-magnesic phosphate; bacteria, in large numbers.

The pain on urination, the frequency of the act, the vesical tenesmus were evidently due to the enlarged prostate, secondary bladder inflammation, and recently developing pyelitis. Inasmuch as the patient was residing in the country, it did not seem to be proper either that he should be inducted into catheter life or that local treatment should be undertaken. The tenesmus and pain were markedly re-

lieved by suppositories of the alcoholic extract of belladonna leaves. The use of diluents, balsamics, and benzoates did not materially alter the physical appearance of the urine. On April 30th, salol was prescribed. In small doses (5 to 7 grains) it was without effect; in larger, blood would appear in the urine. Not only was blood-coloring matter present, but altered red corpuscles could be readily found. When 40 grains per day had been reached there was a total absence of sulphates (barium-chlorid test) in the filtered urine, the color became decidedly darker, but while the frequency of urination was diminished, the urine was quite as ropy and the albumin percentage as high if not higher. Salophen and salipyrin each seemed to be of temporary benefit. Sodium salicylate promptly upset the stomach as did oil of gaultheria and volatile oil of betula. Finally it was thought best to return to salol, which was commenced in 5-grain doses on June 12th.

The report of the examination of the urine on June 28th was as follows: Quantity, 56 ounces (18 urinations); specific gravity, 1017; reaction when examined, alkaline; odor, ammoniacal. Chemical analysis: Albumin present, ½ of 1 per cent. by weight; bile, trace; indican, increased; urea, normal; uric acid, normal. Microscopical examination made June 28th: Casts, few hyaline and finely granular; blood, few altered cells; pus, present in considerable amount; epithelium, considerable amount of bladder, few pelvic cells; crystals, ammonio-magnesic phosphate; bacteria, in large numbers.

Inasmuch as the amount of albumin was readily accounted for by the mucus and pus and there was not evidence of serious renal changes, it was thought best to continue the salol, with such regulation of diet as was practicable, and to make use temporarily of spartein sulphate to assist the heart and promote diuresis. Under this *régime* the summer was passed comfortably and locally satisfactory reports were made until November, when the pain, tenesmus, and frequent micturition returned.

The examination of urine was as follows: Passed, November 2nd and 3rd, quantity, 39 ounces (30 urinations); specific gravity, 1011; reaction when examined, alkaline; odor, ammoniacal; sediment, almost solid with ropy substance. Chemical analysis: Albumin, present almost 1 per cent by weight; bile, traces; indican, increased; blood, coloring matter present; urea, diminished; uric acid, diminished. Microscopical examination: Casts, few hyaline and finely granular; blood, numerous red corpuscles; pus, present in large amount; epithelium, large amount and squamous; crystals, few ammonio-magnesic phosphate; bacteria, plentiful.

Evidently the problem was becoming complicated by renal insufficiency. Urotropin in 7½-grain doses thrice daily after meals was ordered, and the spartein was continued. The diet and instructions as to diluent fluids remained unchanged, but salol was omitted. On November 12th there was a marked change in the urine; the amount had risen to 64 ounces (24 urinations) of a specific gravity of 1016, the ropy sediment was lessened, the sulphates were normal, and blood had diminished. The ammoniacal odor was less marked, but the bacteria were as plentiful as ever. On the 22d, the change was still more marked; the alkalinity was faint, the bacteria in small numbers, as compared with the past, and the amount of ropy material very much lessened. The treatment was continued.

The examination of urine on November 27th was as follows: Quantity, 61 ounces (14 urinations); specific gravity, 1021; reaction when examined, faintly acid; transparency, nearly clear. Chemical analysis: Albumin present, $\frac{1}{10}$ of 1 per cent; bile, trace; indican, slightly increased; urea, slightly decreased; uric acid, normal. Microscopical examination: Casts, few hyaline; pus, in small amount; epithelium, some bladder, few pelvic cells; bacteria, few in number.

Urotropin has been continued, generally in 7½-grain doses twice daily, a part of the time as 10 or 15 grains at bed-time, with occasionally intermission of a day, until the present time. Medication addressed to his circulatory apparatus has been used as required. No untoward symptoms have arisen from so prolonged a use of the drug, and that it has been prolonged and constant has been due to the implicit belief of the patient that this has relieved him of his suffering and his refusal to do without the remedy.

Examination of urine made on June 29, 1898: Quantity, 55 ounces (ten urinations); specific gravity, 1022; reaction when examined, acid; transparency, nearly clear. Chemical analysis: Albumin, trace; indican, increased; urea, normal; uric acid, slight increase. Microscopical examination: Casts, few hyaline; pus, small number of cells; epithelium, few bladder-cells; bacteria, very few.

This is certainly one of the conditions which perplex the physician. The danger of operative interference, the necessary care in local treatment, and the difficulty of keeping catheters aseptic render these unfortunates subjects for earnest thought. The results in this case, and this, although more striking, is but one of several which could be cited, show that the problem has become much simplified. It is evident that urotropin is not bactericidal, but rather inhibits bacterial development.

The extension of the field of usefulness of this drug in preparatory treatment for necessary surgical intervention is left for the surgeon to develop. The frequently unexpected fatality of the minor operations, and even after explorations, show plainly that preliminary treatment is necessary if the surgeon would relieve himself of blame.

The following is an unusual but difficult condition for treatment:

CASE II.—An unmarried clergyman, thirty-one years old, had suffered from various dyspeptic symptoms for more than a year. He was excessively nervous, a light sleeper, exceedingly variable in his

temper, and entirely disinclined to attend to his duties. The immediate cause for his seeking medical advice was his discovery of the fact that he was passing a turbid urine, which was whitish in color, during the morning hours. He had decided that the cause of the turbidity was semen, and that his intellectual and physical end was imminent. On assuring him that true spermatorrhea was one of the rarest of conditions, he became somewhat satisfied.

The examination of urine on March 6th resulted as follows: Specific gravity, 1026; reaction when examined, alkaline; appearance of sediment, "sandy." Chemical analysis: Albumin, absent; bile, traces; indican, increased; urea, normal; uric acid, increased; phosphates, earthy and alkaline, increased. Microscopical examination: Casts, absent; spermatozoa, none (centrifuge specimen); epithelium, small amount of bladder; crystals, ammonio-magnesic phosphate; bacteria, absent.

On boiling the urine the turbidity immediately increased; a small addition of nitric acid cleared it. The night urine was free from turbidity, but contained an increased amount of earthy phosphates. A strictly meat diet was insisted upon, gentian and nitrohydrochloric acid prescribed before meals, an increase of out-door exercise, and freedom from anxiety declared to be necessary. On the 19th, there was substantially the same report. The urine showed a small amount of phosphates during the morning hours, but still sufficient to make it turbid when voided; it was still alkalin up to noon. Recalling the fact that urotropin is one of the drugs upon which most reliance can be placed as an urinary acidifier, 10 grains were ordered to be taken after each meal. The other remedies were continued, for the patient was verging upon insanity, so excited had he become about his "muddy" urine. Three days later (22d) he reported that his urine was entirely clear during the whole twenty-four hours. The gentian and nitrohydrochloric acid were now omitted; the urotropin was continued.

On March 31st the examination of urine showed: Specific gravity, 1021; reaction when examined, acid; transparency, clear. Chemical analysis: Bile, absent; indican, slight increase; urea, slight increase; uric acid, normal; phosphates, earthy, slight increase; alkaline, normal. Microscopical examination: Epithelium, few bladder-cells.

Urotropin was continued in 15-grain doses night and morning. April 29th he reported that there had been no recurrence of symptoms; medication was then stopped. On June 15th the report was made that the patient had remained entirely well since his last report.

While it is undoubtedly true that recovery would have taken place under the classical treatment, it is equally true that the prompt and absolute clearing up of the phosphoturia under urotropin produced so marked a mental impression that further progress was rapid toward recovery. Notwithstanding this, there is no reasonable doubt that this is a remedy of remarkable potency for the clearing up of phosphatic urine.

Case III.—A young man, aged twenty-four years, reported that six days before he had noticed an urethral discharge which had come on four days after an illicit connection. He had been treated by a physician who had given him injections and internal medication until he could neither eat nor sleep. He was nauseated, suffered from incessant pain in the bladder, had a continued desire to pass water, which, when accomplished, resulted in the voiding of a small amount, and of severe smarting. Physical examination revealed a copious urethral discharge, yellow in color, and of a thick consistency. Microscopic examination of the discharge revealed large numbers of the gonococci (Neisser's method). The examination of urine on June 2d showed: Specific gravity, 1018; reaction when passed, alkaline; transparency, cloudy. Chemical analysis: Albumin, full trace; blood, small quantity. Microscopical examination: Blood, many red corpuscles; pus, in abundance; epithelium, large amount of bladder; bacteria, in great abundance.

The inflammation was altogether too vigorous to permit the use of the endoscope. Silver citrate (Credé) in 1-per-cent. solution was injected every four hours by the patient, this being preceded by an injection of the official solution of hydrogen dioxid and lime-water in equal parts. Internally urotropin was prescribed in 7½-grain dose four times daily. On the 4th it was reported that the urine could be retained for an hour, the pain was markedly lessened, the appetite had returned. Gonococci were still numerous. The urine was natural, but contained no blood. On the 6th, the patient claimed that there was great relief from the pain and dysuria, and that the discharge had almost ceased. After preliminary irrigation with normal saline solution an endoscope of small caliber was inserted and the entire urethra found to be actively inflamed so far as the instrument reached. The discharge still contained a few gonococci. Two days later it was possible to make a thorough exploration with the above precautions. The urethra was uniformly reddened and still quite sensitive. No gonococci were found (4 slides, Neisser's stain).

The examination of urine on the 8th showed: Specific gravity, 1020; reaction when passed, acid; appearance of sediment, slightly flocculent. Chemical analysis: Bile, trace; indican, increased; blood, absent. Microscopical examination: Pus, few cells; epithelium, few bladder-cells; bacteria, in small number.

The instructions for treatment were repeated, and on the 10th he again reported still further improvement. The endoscope showed that the urethritis had quieted considerably. Urine could be retained for three hours. On the 15th, there was no discharge, and but little burning on urination. On the 20th, injections were discontinued. Four days later all symptoms being relieved, all medication was omitted. On July 8th, no gonococci were

found on stripping the urethra, no symptoms had returned and the patient was released from attendance. The disappearance of the gonococci within six days is doubtless distinctly chargeable to the silver citrate. But as that has no effect upon the inflammation, either of bladder or urethra, it seems best to administer internal remedies. The correction of the excessive alkalinity of the urine, undoubtedly brought about by the careless administration of alkalies, and the irritation added to, possibly by neglect of dietary precautions, had brought this patient to a deplorable condition. Urotropin cleared the urine with promptitude and the good effects continued.

CASE IV.—A young woman, aged twenty-four years, was delivered of a girl some two years after her marriage. The labor which occurred in December, 1897, was uneventful. She recovered well, except for a pain which was severe in passing urine, a constant desire to urinate, and pains in back and limbs. For these symptoms she had been treated locally and internally by the physician who attended her. On February 24th, she came under observation for these and symptoms which might indicate renal disease. The examination of urine on February 24th, showed: Quantity, 41 ounces; specific gravity, 1026; reaction when examined, neutral; appearance of sediment, much, flocculent. Chemical analysis: Albumin, ⅛ of one per cent. by weight. Microscopical examination: Casts, few finely granular; blood, few cells; pus, small quantity; epithelium, plenty of bladder, and some pelvic; crystals, few ammonio-magnesic phosphate; bacteria, in abundance.

Inasmuch as there was a likelihood of bladder infection and secondary pyelitis through catheterization, on four or five occasions during the puerperal month, by the nurse, it was thought best to clear the urine in order, if possible, to get more definite information as to the kidneys. Urotropin in 15-grain doses was given twice daily. Nearly a month later (March 22nd), she reported, saying that all symptoms had disappeared within a week of her visit, but that she had continued the remedy one week longer. During the time which had elapsed there had been no return. The examination of urine March 22nd, showed: Quantity passed in 24 hours, 49 ounces; specific gravity, 1017; reaction, acid; appearance of sediment, flocculent. Chemical analysis: Albumin, ⅛ of one per cent. by weight. Microscopical examination: Casts, few finely granular, few epithelial and many hyaline; epithelium, very few bladder-cells.

The history seemed to point to the fact that an infection, involving both the bladder and the pelvis of the kidneys, had taken place in a woman whose kidneys were previously diseased. This local treatment had not benefited. Within one week the bladder was relieved, she received treatment for a second week and remained well for two weeks without medication. The patient is now under treatment for the renal difficulty.

From a study of the above observations and of others, it seems fair to present the following conclusions:

1. Urotropin produces no untoward symptoms when administered in amounts of 30 grains *per diem*.

2. It renders an alkaline urine acid no matter what the cause may be.

3. It inhibits the development of the micro-organisms of ammoniacal cystitis and in this way clears up cloudy urine.

4. It is indicated as a preparatory disinfectant in operations upon the urinary tract; in pyelitis, cystitis, and other inflammation of the urinary tract irrespective of their cause in phosphaturia, and in other conditions tending to formation of urinary calculi.

CLINICAL OBSERVATIONS IN REGARD TO GENERAL ANESTHESIA BY THE SCHLEICH MIXTURES.[1]

BY HENRY J. GARRIGUES, M.D.,
OF NEW YORK.

IF any one should doubt the propriety of bringing the subject of anesthesia before a gynecological society I would answer that not only a great part of the gynecologist's work is operative, and that consequently he is interested in the use of anesthetics, but that his operations often are of unusual duration as compared with other surgical operations, and that he often has recourse to the Trendelenburg position, which entails particular dangers in regard to anesthesia. And, furthermore, the special anesthetic which is the subject of this investigation recommends itself particularly to the gynecologist for diagnostic purposes, as will be shown later.

This Society offers, also, the special advantage of being a national society, counting among its members some of the greatest operative gynecologists from nearly all parts of the country, so that it is particularly fit for testing the value of a new anesthetic.

The question of anesthetics has evoked consider-

[1] Read at the Twenty-third Annual Meeting of the American Gynecological Society, held at Boston, May 24, 25, and 26, 1898.

able interest of late years. Ether, on account of its threefold greater safety, is constantly gaining ground as compared with chloroform; but some have in the mixture of both with the addition of absolute alcohol —the so-called A C E mixture—thought to be found the best of all anesthetics, its record as to safety having distanced all others

As opposed to general anesthesia, which by its very nature contains an element of danger to life, Dr. Schleich[1] of Berlin, in 1894 strongly advocated a much more extensive use of local anesthesia and discovered the anesthetizing power of solutions containing so small an amount of cocain and morphin that the element of danger is eliminated. The whole procedure is, however, so complicated that it is very unlikely to become of any great importance in the kind of work with which we are concerned.

On the other hand, this same Dr. Schleich has investigated the physical laws that underlie general anesthesia, and indicated new mixtures which he claims are preferable to any general anesthetic hitherto in use. He says it is evident that an anesthetic which evaporates rapidly can be rapidly eliminated through the respiratory tract, whereas a slowly evaporating gas must stay longer in the body and is more apt to cause a dangerous accumulation. According to his theory, the composition of the anesthetic should, therefore, be such as to have a boiling-point proportioned to that of the body. For quite short operations he recommends the use of an anesthetic that has a boiling-point identical with the temperature of the body, and for long operations one with a boiling-point 2° or 3° C. (3.4° to 5.4° F.) higher, which latter he also recommends for patients with fever.

Schleich says, also, that the chemical reaction of the saliva shows that in mixtures of fluids with low boiling-point with others with high boiling-point, the latter are carried along by the former, so that they are eliminated much faster than they would be if used alone.

Chloroform has the high boiling-point 65° C. (149° F.), while sulphuric ether has the low boiling-point 34° C. (93° F.) By experimenting with different fluids he came to the conclusion that the best anesthetic was a mixture of chloroform, sulphuric ether and petroleum ether at a boiling-point between 60° and 65° C. (140° to 149° F.).[2] He chose petroleum ether because he had found in experiments on animals that we do not possess any other ethereal substance of which such astonishing quantities may be injected hypodermically without the occurrence of serious disturbances. He uses these three substances in different proportions constituting his three mixtures:

Mixture I.—Boiling-point 38° C. (100.4° F.):

	Parts by Volume.
Chloroform	45
Petroleum ether	15
Sulphuric ether	180

Mixture II.—Boiling-point 40° C. (104° F.):

Chloroform	45
Petroleum ether	15
Sulphuric ether	150

Mixture III.—Boiling-point 42° C. (107.6° F.);

Chloroform	30
Petroleum ether	15
Sulphuric ether	80

It appears from these formulæ that Mixture I. contains $\frac{3}{16}$ chloroform—that is, a little less than $\frac{1}{5}$; Mixture II., $\frac{3}{14}$, or a little more than $\frac{1}{5}$; and Mixture III., $\frac{6}{25}$, or a little less than $\frac{1}{4}$.

The first to call attention to this new anesthetic in this country was Dr. M. L. Maduro,[1] who had had the opportunity of seeing it administered in Schleich's clinic. In a later paper[2] he unfortunately stated that rhigolen could be used instead of petroleum ether. This was due to the mistake that rhigolen, which has the low boiling-point of 70° F., was thought to have that of 70° C. Such statement not being revoked has, perhaps, led others like myself to experiment with a wrong and dangerous mixture. I used it in a number of cases before my attention was called to the error by the manufacturer of both rhigolen, and petroleum ether. Later Dr. Maduro read a paper embodying his experience with a hundred cases before a society in Philadelphia.

Dr. W. Meyer read a paper on Schleich's method before the New York County Medical Society on December 27, 1897, based on his experience in 100 cases, and accorded unstinted praise to the new anesthetic, which he declared to be a solution, not a mixture.[3] He was, however, later informed by Dr. H. P. Weidig, that No. I. contains 53.76 per cent. in volume of free ether; No. II., 44.64 per cent., and No. III., 36.96 per cent.[4] According to his latest communication he now uses only a mixture of 43.25 per cent. by volume of chloroform, and 56.75 per cent. of sulphuric ether, which form a molecular solution, which he gives by the continuous drop method.[5] It will be noticed that this abandonment of Schleich's mixtures is exclusively based on theoretical grounds. From his practical experience in upward of 100 cases he was "delighted with the improvement in general anesthesia by means of these

mixtures, and tried to induce his colleagues also to make use of the same for the sake of their patients."

Drs. Stillmann and Greeley have reported forty-four cases anesthetized by the Schleich method in the New York Infirmary for Women and Children. The average length of the operations was fifty-two minutes; the average amount used to produce anesthesia was seven-eights of an ounce; the average amount used in all, three and one-third ounces; the average time it took to produce anesthesia was ten and one-half minutes, and consciousness returned on an average in fourteen minutes. Eighteen patients were considerably nauseated during twenty-four hours after the operation, three of them more so than after other anesthetics administered at previous operations. Mixture I. was used in 24 cases, Mixture II. in 16 cases, and Mixture III. in 4. The muscular reflexes were difficult to control with No. I., and Nos. II. and III. "would be used in a larger proportion of cases again." They used Esmarch's mask covered with flannel and oiled muslin. With few exceptions the patients received $\frac{1}{8}$-grain of morphin and $\frac{1}{150}$-grain of atropin half an hour before the operation. It will appear in the following that in entirely similar operations we used much more frequently the weakest solution, needed much less to produce anesthesia, produced it in much shorter time, and had much less vomiting.

Schleich's theory that the danger of the different anesthetics chiefly is due to the difference in their boiling-point, and that the composition of the mixture should be decided by the patient's temperature, may be questionable, and it will be seen in the following that my personal experience does not always bear out that theory. My investigation has been purely clinical. Having for many years taken a deep interest in the question of anesthetics, and being persuaded that our present methods were open to great improvement, as soon as I read Dr. Maduro's report of the Schleich anesthetic I made arrangements with my colleagues at St. Mark's Hospital to give it a fair trial, and without enthusiasm or prejudice to try to obtain material enabling me to form an opinion as to its merits and drawbacks, based on facts accurately observed and systematically recorded. In this work I have been ably assisted by Dr. C. J. Buddeke, a member of the house-staff, who, when other engagements prevented my presence, has carried out the investigation on the lines traced by me. In this way we observed and recorded 100 cases, which form the base of the following report.

With any kind of anesthetic we have to take into consideration first of all, safety; secondly, speed; thirdly, the comfort of the patient; fourthly, simplicity, and, finally, economy. The safety of the new method cannot be proved until it has been used many thousand times and its record made up in conformity with that of the other anesthetics. So far we can only state that no case of death has been reported with the Schleich mixtures. Like all other anesthetics, that of Schleich contains, however, an element of danger. We cannot make that profound impression on the brain which is needed to abolish sensation without coming dangerously near paralyzing the centers of respiration and circulation. But so far as my observation goes as to the appearance of the patient, the absence of struggling, the condition of the respiration, the pulse, the pupils, and the urine, the promptness with which consciousness returns after the withdrawal of the anesthetic, and the unparalleled comfort of the patient after the return of consciousness—all this leads me to look upon the new anesthetic as less dangerous than any one we have known hitherto. In regard to speed, it ranges between chloroform and the A C E mixture.

As to the patient's comfort, it is simply amazing. Where we used to see patients lying insensible for hours, leaning over the vessel destined to receive their vomit, we find them now lying quietly on their backs, or see them sit up or leave the hospital or office in a short time without even needing a companion. Our nurses soon found out how much less attendance was needed on their part with the Schleich mixtures, and patients who had tried ether and chloroform on other occasions found the Schleich mixture much pleasanter than either of them. In regard to simplicity, the new method leaves nothing to be desired, a common Allis ether-inhaler or the paper and towel cone being all the paraphernalia called for. In private practice it does not make much difference if one anesthetic costs a few cents more than another; but in the budget of a hospital the item of anesthetics is a very large one, and the comparative cheapness of the Schleich mixture is another point in its favor. The price of chloroform is $1.08 per pound, that of ether 99 cents, and that of petroleum ether only 50 cents. The combination costs a little less than ether, and very much less is used of it.

The mixture may be used in every case in which general anesthesia is not contraindicated. The age of our patients ranged from ten to eighty years. Three had heart disease, 1 stenosis of the aorta, 1 a fatty heart, and 1 accentuated second sound; 2 had marked arteriosclerosis; 4 had lung trouble, 2 bronchial breathing; another sibilant râles, and a fourth absence of respiratory murmur on the right side. In seven cases the urine was more or less al-

buminous before the administration, and their condition was in no way made worse by it, and in not a single case did there appear albumin when it had not been there before. If this seems to prove too much, since albumin and casts are found frequently after longer operations, especially when chloroform has been given, I must state that the urine was examined in every case, but not before the next day, and then it was found normal if it had been so before the operation. In two cases there was a trace of sugar in the urine before the anesthetic was given, in one of which it had disappeared after. There was one alcoholic. He offered no resistance, was anesthetized in seven minutes, and needed only 20 c.c. of the weakest mixture. In twenty cases the general condition of the patients before operation was only fair, and in nine it was decidedly bad.

In an institution like St. Mark's Hospital there was of necessity a great preponderance of serious operations, such as laparotomies, hysterectomies, removal of the appendix vermiformis, pylorectomy, gastrostomy, etc. Many of these operations were difficult and required much time. The average duration was 52 minutes, but in 13 cases it was between 1 and 2 hours, in 4 between 2 and 3 hours, and in 1 even 3½ hours. Frequently Trendelenburg's position was used. In an empyema operation with total absence of respiratory murmur on one side, the patient was lying on the healthy side, and in another case the patient had to be laid partly on the side and partly even on the abdomen during a bloody operation lasting fifty minutes.

I have tried different forms of inhalers. An Esmarch chloroform mask covered with flannel and oiled silk, through which goes the nipple of a baby-bottle from which the end has been cut off so as to form a funnel, has been recommended by those who use the drop method. The solution dissolves, however, the resinous part of the oiled silk, and I therefore replaced it by sheet-rubber, which worked well; but it is often difficult to hold the bottle just over the little funnel so as not to miss it. Maduro uses the well-known American towel-and-paper inhaler, which has the advantage of being always improvised, and therefore, clean and odorless. It has, however, to be removed from the face in order to pour on the anesthetic. I soon came to the conclusion that Allis' ether-inhaler worked best of all. It is, under ordinary circumstances, never removed from the face during the administration of the anesthetic. In the beginning the top is left open, so that the patient gets plenty of air and is not frightened. Later, when he is half or totally unconscious, the top is folded together, and is kept closed or opened according to the condition of the patient. We use the double-tube attachment to the bottle, by which one can easily pour the fluid out drop by drop, or in a thin stream. We start with a few drops, and soon proceed at such a rate as to administer on an average 1.5 c.c. every half minute.

In the beginning we followed Schleich's rule about choosing a solution the boiling-point of which was proportioned to the temperature of the patient; but I soon found that we could anesthetize our feverish patients as well with the weakest solution. In one woman the temperature was 103.6° F., and still it took only six minutes to anesthetize the patient with No. I., and only 20 c.c. were used. Differing from others who have reported their experience, we have, therefore, used No. I. nearly exclusively—ninety cases. No. II. was only used once, in the case of a patient with a temperature of 99.8° F. No. III. was used in six cases, one patient having a temperature of 104.8° F., two 102° to 103° F., and two 99° to 100° F., and the sixth normal temperature. In three cases we began with No. I. and changed to No. III., in the two when anesthesia had not been obtained in ten minutes, and in a third after thirty-eight minutes, because it was not deep enough. I have, therefore, made it a rule to begin with the weakest solution in every case, and if anesthesia is not produced in ten minutes to substitute the strongest. In private practice it is advisable to have the three ingredients in separate bottles, and a measuring-glass divided in 100 c.c. If Mixture I. does not keep the patient immobile, or the muscular relaxation is unsatisfactory, transition is likwise made from Mixtures I. to III. No. II. seems superfluous to me. In spite of our using Allis' large cone, pouring the fluid on intermittently in a stream and using the weakest solution, we have used much less of it than others. The average amount used to produce anesthesia has been 17.45 c.c., a little over half a fluidounce. The lowest amount was 7.5 c.c., the highest 35 c.c. In the large majority of cases from 15 to 20 c.c. sufficed. In the one case in which Mixture II. was used, a patient with a temperature of 99.8° F., 25 c.c. were needed to produce anesthesia. Of the six patients who received Mixture III., two had 10, one 15, and three 30 c.c.

The total amount used during the whole operation has been much smaller than that of others. While Drs. Stillmann and Greeley used on an average three and a half ounces (105 c.c.) for an average time of fifty-two minutes, and Dr. Meyer from six to eight ounces for operations lasting from forty to sixty minutes, we have only used on an average 50.91 c.c. for an average time of fifty-two minutes. Minimum, 20 c.c.; maximum, 130 c.c. Unfortunately, most operators are in a hurry to begin their opera-

tions and are very apt to be unreasonable in their demands on the anesthetist at the peril of the patient's life. Rapidity of action is doubtless the chief reason why so many surgeons still use chloroform after its much greater danger as compared with ether has been proved by statisties embracing many thousand cases.

With any kind of anesthetic there will, on account of individual peculiarities, always be patients who require much longer time than others to be safely anesthetized. I operated once on a lady, and an assistant who had had considerable experience at the Charity and Maternity Hospitals in giving both ether and chloroform gave chloroform for me during three-quarters of an hour without obtaining unconsciousness, but causing tetanic contraction of the muscles. We then changed for ether, which had to be given during half an hour before the patient was anesthetized. In another case I personally gave ether for half an hour without abolishing sensation, and had then to change to chloroform. In a third case anesthesia could not be produced at all. It was an apparently strong, healthy woman, forty-two years of age, who in former years had had attacks of petit mal. We tried in vain Schleich's mixture, ether, A C E mixture, and Cole's mixture of ether and oxygen. Whatever we tried had the same effect, namely, that the moment consciousness became slightly dimmed she stopped breathing altogether. If speed shall decide the choice of the anesthetic, it seems that the gas-ether method must be awarded the palm, since it is claimed that the patient is ready for operation in two minutes. I have no personal experience with this combination, but the difficulties inherent in the administration of nitrous-oxid gas will at best limit its use to hospitals, and there remains, of course, all the undesirable effect of ether anesthesia—the frequent vomiting, the unpleasant taste, lasting for twenty-four hours, and the inextinguishable thirst.

Compared with other anesthetics, the Schleich mixtures have given us entirely satisfactory results in regard to the time needed for anesthetizing the patients. Not only has our average been six minutes, but six minutes has by far been the time most frequently required. Our minimum has been two minutes and our maximum seventeen minutes. This last length of time was needed in a woman whose temperature was 101° F., and who was in a low condition on account of puerperal sepsis. We have very rarely needed over ten minutes, and such cases occur just as well with ether and chloroform. The one patient who received Mixture II. needed it nine minutes; with No. III., four, six, seven, nine, thirteen, and fifteen minutes respectively was needed; in the two cases in which No. I. was changed for No. III., after fourteen minutes, four additional minutes was required. Our average of six minutes is considerably shorter than that given for ether by Dr. B. B. Brouner,[1] in his excellent article on "Rational Etherization," with which I fully agree. His average time was eight and a half minutes. There has been remarkably little excitement before unconsciousness was produced. Only two showed a slight degree, and three others struggled a little. In the only alcoholic patient we had there was no struggling at all. There has been much less accumulation of mucus in the mouth and throat than with ether. Only in two cases has it been abundant; in four, moderate; and in six, slight.

Schleich claims that there is no cyanosis at all with his method. We have, indeed, not had a single case of that pronounced blueness so often observed during other anesthesia, especially in Trendelenburg's posture. But we have recorded slight cyanosis in three cases and moderate in three, one of which was in Trendelenburg's position, and the other in the knee-chest position. There is also much less vomiting than when ether or even chloroform is used. In 69 per cent. there was no vomiting at all; in 27 per cent. it was slight; in 2 moderate; in 1 it lasted an hour and a half, and in another case it was considerable, but in not a single one severe. One patient had eaten a full dinner three hours before being anesthetized, and still he did not vomit and felt perfectly well shortly after the operation. I have not been able to find a constant influence on the pulse. In many of our cases the excitement of having to undergo an operation would cause a frequency of pulsation, which gave way to a normal pulse under the influence of the anesthetic. In many others we counted a few more beats per minute at the end than before beginning, and in a large number a few less. As to the volume there is a tendency to diminution, but we have not had a single case in which it had a serious character.

The real danger with Schleich's mixtures as with other anesthetics lies in its influence on the respiration. The frequency of the respiratory movements was invariably increased—minimum 24, maximum 65, commonly between 30 and 40 per minute. In three cases we have had arrest of breathing, which, however, easily yielded to artificial respiration by Sylvester's method, inhalation of oxygen, and hypodermic injection of strychnin. In one of these cases $\frac{1}{6}$ grain of morphin and $\frac{1}{150}$ grain of atropin had without my knowledge been injected under the skin two minutes before beginning the anesthesia. Opinions are much divided about the value of the pre-

[1] W. B. Brouner, *Medical Record*, January 29, 1898.

liminary administration of narcotics before giving anesthetics; but under all circumstances at least twenty minutes should have elapsed since the narcotic was given before anesthesia is begun. Otherwise we risk getting an incalculable cumulative effect. The second case was that of a very fat man with fatty degeneration of the heart and albuminuria. The third was a young woman with hyaline and granular casts in her urine, who was being examined with the cystoscope. Upon the same patient I later performed Alexander's operation without having any trouble from the same anesthetic. In a fourth case the respirations became very superficial, and similar means as the above-mentioned were used to bring it back to the normal type. In three of these four cases the administration of the anesthetic was resumed and continued till the end of the operation. The respiration should be watched carefully and constantly. Not only deep and frequent respirations are a warning that the patient needs more air, but slow and superficial breathing is of still worse purport, and should be met by immediate intervention or discontinuance of the anesthetic and employment of the usual remedies for failing respiration. We also watched the pupils very closely. In nearly all cases they were contracted, but in two they were dilated, and in five they were alternately dilated and contracted. According to Schleich (*loc. cit.*, p. 65) the contracted pupil is that of natural sleep, the dilated is found in poisoning with carbonic acid. He says, therefore, that when the pupil is dilated the cone should be removed, so as to admit more oxygen. This would, however, not have been possible in those cases in which it was dilated all the time. But the dilated pupil being also that of death, I hate to see it, and am particularly watchful when it appears.

One of the greatest advantages of the Schleich method is the rapid return to consciousness and a normal condition. The average time at which the patients regained consciousness was fifteen minutes —minimum, one minute; maximum, forty minutes; most frequently, nine minutes.

The ease with which the patients take the anesthetic and the rapidity with which they return to a normal condition, in which respect it is only surpassed by nitrous oxid gas, is of particular value to the gynecologist, as it will induce him to extend the use of the valuable examination under anesthesia and make the undesirable exploratory incision rarer and rarer.

The outcome of my investigation is, then, that the Schleich mixtures are easily taken; that they may be used in all cases in which general anesthesia is not contraindicated; that anesthesia can be induced in a short time and kept up with small amounts of the fluid; that there is little accumulation of mucus, little vomiting, hardly any cyanosis; that there is no bad effect on the kidneys; that the heart is not much influenced by it, although somewhat weakened; but that there is some danger in regard to respiration, although apparently not more so than with other anesthetics; and finally, that it affects the patient much less than ether or chloroform. I can, therefore, recommend it for general use. Its advantages are so great that it ought at least to have a fair trial and only be condemned for cause.

SIMPLE AND MALIGNANT JAUNDICE OF PREGNANCY; REPORT OF THREE CASES.[1]

BY W. B. YOUNG, M.D.,
OF BON AIR, TENN.;
PROFESSOR OF GYNECOLOGY AND ABDOMINAL SURGERY IN SEWANEE MEDICAL COLLEGE.

DURING pregnancy simple jaundice is observed frequently, but the malignant form remarkably rarely, if one can rely upon text-books and medical periodicals. Fortunately, I had never seen jaundice as a complication of pregnancy until within the last few months. My experience with this disease is sufficiently unique to cause me to report the cases to this Society. The literature I have examined has very little to say upon this subject. In a diligent search through the files of the MEDICAL NEWS from 1888 to 1898 I found only one short article upon jaundice during pregnancy. Looking through the files of the *American Journal of Obstetrics* for 1891, 1892, 1893, and 1894, and the *American Gynæcological and Obstetrical Journal* for 1895, 1896, and 1897, I failed to find one word upon the subject of simple or malignant jaundice of pregnancy. I also looked over all the exchanges at my command, the *Medical Council*, *Southern Practitioner*, *Cincinnati Lancet-Clinic*, *Philadelphia Medical Journal*, *Virginia Semimonthly*, *Nashville Journal of Medicine and Surgery*, and some others, and found them also as silent as the grave upon the subject. It is true I might have overlooked the matter in some of the journals, but hardly think so.

Winkel, in his book on midwifery, page 255, says: "Jaundice is a rather rare disease of pregnancy." He has observed it only once in the catarrhal form, and of an aggravated type. Carl Braun observed the grave form only once in 28,000 pregnant women. Spoeth saw the disorder only three times in 14,061 pregnancies, Duncan once in 10,000 cases, and Winkel once in 16,000 cases.[2] All the authorities, I believe, agree that the same

[1] Read before the Upper Cumberland Medical Society, at Carthage, Tenn., May 5, 1898.
[2] "American System of Obstetrics," vol. i, p. 427.

cause or causes that bring on an attack in the non-pregnant woman will produce it in the pregnant, other things being equal.

In the "Practice of Medicine" by Wood and Fitz I find the following statement in regard to the etiology of the affection: "Mainly through the researches of Staddelmann it is now generally admitted that all cases of jaundice are due to the obstruction to the outflow of bile from the liver and the absorption of its pigment through the lymphatics of the liver, for there is no absorption of bile when the common bile-duct and the thoracic duct are tied." This has reference to simple jaundice. Carreau, in the MEDICAL NEWS of August 1, 1891, makes this statement in regard to the malignant form: "As to the pathology of grave jaundice two factors are necessary, the blood and the bile, but experience has long since proven that the mixture of these two bodies is inoffensive. The symptomatic yellowness, due to the biliary retention, may last for weeks and even months without altering, sensibly, the health, when all at once, under some unknown influence, the phenomena of grave jaundice show themselves and carry off the patient in a few days."

In my experience the prognosis in jaundice in pregnancy must be seriously guarded. Dr. John T. Winter concludes that every case of jaundice occurring in pregnancy should be looked upon as serious, jeopardizing both mother and child. Jaggard of Chicago says the prognosis in simple jaundice should be guarded in view of the unfavorable influence exerted by pregnancy upon the cause of the disease. He also states that it is doubtful whether an authentic case of this disease (grave jaundice) has ever terminated in recovery.[1] Grandin and Jarman state that "pregnancy is rarely complicated by icterus, but the disease assumes special importance from its tendency to become a malignant type," and the prognosis must always be guarded. Lusk says: "Icterus, although a phenomenon of rare occurrence during pregnancy, is interesting and important on account of its tendency to precede or to accompany the fatal pathological changes and symptomatic events connected with acute yellow atrophy of the liver." Playfair observes: "The chief anxiety in regard to jaundice in pregnant women is that it is the frequent precursor of the serious disease (grave jaundice), and that in this affection the prognosis as regards the mother is as bad as anything can be, very few cases, and these of doubtful character, having recovered." When a simple icterus takes on a malignant type it is very insidious, but within a short time it becomes rapid in its progress, and the woman is often in a fatal condition before the physician is aware of her imminent danger.

Grandin and Jarman give the following description of this change: "The transition of a simple icterus into the malignant form is gradual, and usually manifests itself by rise of temperature, this being absent in case of simple icterus. Cerebral symptoms rapidly develop, such as headache, difficulty in breathing, and delirium. The cause of the disease is rapid toward a fatal termination in a few days. The treatment can simply be symptomatic. It avails nothing to empty the uterus either in the interest of the mother or child."

The three cases I am about to report developed within a few days of each other, and the victims lived in the same little village not more than 100 yards apart. In the discussion of this paper I would like the members to take notice of this fact: Might there not have been a local cause? Two of the women, Cases II. and III., were twin sisters, and lived in the same house. Has the disease a hereditary tendency? The first two were supposed to be cases of simple jaundice, and were treated as such, but the first few days proved to be the prodromata of the fatal malady.

CASE I.—Mrs. B. D., aged thirty-five years, blonde, weight about 120 pounds; mother of ten children; six-months' pregnant. Ever since I first knew her she had been in reasonably good health. Being poor, she did her own housework, and took in washing to help support the family. During the six months of her pregnancy I was not consulted. About January 10th she called me in as I was passing and said: "I want you to give me some medicine, for I have 'yaller janders,'" and indeed she had developed a true case of icterus. I prescribed diuretics, baths, and the remedies ordinarily used in treating jaundice. I heard nothing more of her until January 20th, when I was sent for. On my arrival I found the jaundice much increased. She complained occasionally of great pain in the region of the stomach, and of severe headache. Everything looked yellow to her, and almost all the symptoms of an aggravated case of icterus were present. There was no elevation of temperature. Her pulse was about 80 and her bowels were acting, but the discharge was of a distinctly clay color. Her urine was scant and very highly colored.

She seemed to be in remarkably good spirits considering her serious condition, laughing and jesting with the family. Her high spirits without elevation of temperature and without any indication of secondary cerebral symptoms caused me to not regard it as a malignant case. I increased my efforts as above described. This visit was made at about 10 A.M. At 3 P.M. her condition suddenly became worse, and the family sent for her husband who was at work in the mines. I was not notified of the change in her condition until 9 P.M. The messenger then failed

[1] "American System of Obstetrics," vol. i, p. 420.

to inform me of the existing danger. He simply stated that she was no better and was suffering from severe pains in the stomach. At this hour I was very busy and sent her two tablets of sulphate of morphin, one-fourth of a grain each, and directed that one tablet be given at once and the other in two hours if she was not relieved. Should this fail to give her ease I was to be called. I was not summoned again until 5 o'clock the next morning, when I hurried to her bedside, as the messenger said he thought she was dying. When I reached the house I found the patient in profound coma, with stertorous breathing, respiration 22, and pulse 100, and feeble. I did not take her temperature. Her skin was of that characteristic dull yellow color, almost coppery, that accompanies the symptoms of cerebral origin. It was at this visit that I could see the fatal end. Her feet, legs, arms, and hands were very much swollen by this time, but had not been at my former visit. They continued to swell rapidly until death occurred. Both tablets of morphin had been administered during the night, as directed. From the husband I learned that she suddenly become unconscious about 9 P.M., and was quite delirious for a short time, then falling into a deep sleep, and from that hour until her death, which occurred January 21st at 2 P.M., seventeen hours later, she never spoke nor moved a muscle, being in profound coma. I made another visit at 11 A.M. and found her in about the same condition as at 5 A.M., except that she was almost pulseless. Every muscle remained as if paralyzed. When the hand or foot was raised it would drop lifeless on the bed. A dark fluid, similar to coffee grounds, was flowing from her mouth. The family told me this had continued for some hours, and they were confident that at least a pint of this fluid had been discharged. It continued to flow until her death. There was no discharge from the vagina until a short time before she expired, and this consisted of a small quantity of dark bloody fluid.

Case II.—Mrs. T. D., aged twenty-four years, had had one abortion one year before. When I saw her she was eight-months' pregnant. On January 25, 1898, I found her in bed suffering from a well-marked case of icterus. She complained of general soreness and pain in the region of the stomach. Her pulse was 88, and was quite feeble; temperature and respiration normal; urine scanty and high colored, and gave pain when voided. She had been vomiting freely the previous night. The vomitus was of a dark color, resembling coffee grounds. The bowels had moved four or five times during the night, and the discharge was of a dark color and waxy consistency. The husband had given castor oil the day before. I ordered hot baths and gave her phosphate of soda, with a diuretic. She had a ravenous appetite but nothing would remain on her stomach.

On January 26th, in the early part of the morning, she was confined. I was called at 6 A.M., but before I started a second runner came and said that I need not go, so I did not reach the patient until 3 P.M. I found that a female child had been delivered by a midwife. It was very much jaundiced, and was quite a puny looking object, at the end of thirteen days weighing only two and a half pounds. It did not seem to have strength to nurse, and lived only about six weeks. The midwife stated that the patient had the easiest labor she had ever witnessed; that the child was born with one or two pains. The placenta came without delay or difficulty. At 3 P.M. her pulse was 110, and feeble; her temperature, 98.7° F., and her respiration normal. The jaundiced condition had increased very much since the day before. Her appetite continued ravenous, but the vomiting persisted. Her bowels moved once during the night and I was informed that the passage was still dark and waxy. She complained of pain in the stomach and of being drowsy. On January 27th I saw her at 1 P.M., and found her unconscious and very delirious. Her pulse was 92, still feeble; her temperature, 97.8° F., and respiration normal. Her face was considerably swollen and her feet and hands were beginning to swell. Her husband said she continued to vomit the black material until 2 P.M., when she became unconscious and did not vomit any more during her sickness. She was continually grinding her teeth and had been since she became delirious. During the previous night the family thought she had two "spasms." Twice during the night there was involuntary discharge of feces and urine.

On January 28th I visited her at 1 P.M. She was still unconscious. Pulse 110; respiration normal. I did not take her temperature, having broken my thermometer. Hands, feet, and face still swollen. There was much eructation of very offensive gas. Her bowels had not moved since my last visit. She was still grinding her teeth. She would take water, milk, or medicine into her mouth, hold it for a short time, and then spit it out, refusing to swallow. She did not recognize any one during the day, when aroused. On January 29th at 11 A.M. her condition was practically the same. During the night her attendants succeeded in getting her to swallow some of the medicine and a little milk. The bowels were still locked, but there had been involuntary discharge of urine. Pulse 104; respiration normal. January 30th, 2 P.M., patient remained about the same until early in the morning, when all at once, without being spoken to, she awoke from her stupor and recognized several of her friends. She spoke only with great effort, but took her medicine and food nicely from this time on. She complained of pain in the region of the stomach. The bowels and kidneys acted normally. Pulse 120; temperature 99.8° F.; skin still very yellow. January 31st, 10 A.M. Patient somewhat improved. Pulse 120; temperature 98.6° F. The pain in the stomach continued; her speech was very slow and labored. February 2d. Patient's condition much improved. Pulse 98; temperature 97.6° F. Bowels and kidneys acting normally; skin clearing up. She talked and laughed with comparative ease. Tongue becoming clean; no pain; appetite returning. February 4th, 1 P.M.

I found the patient laughing and talking with friends. Skin clearing up nicely. Pulse 96; temperature 99.2° F. She said that she felt perfectly well but that the previous few days were a blank in her memory. Appetite good; bowels and kidneys acting well; swelling had about left her face, hands, and feet. February 7th, complete recovery.

CASE III.—Mrs. J. D., aged twenty-four years, married seven years; had had two children and one abortion; three-months' pregnant. I was called to see her January 28, 1898, and found her suffering from simple jaundice. I prescribed hot baths, light diet, and diluted muriatic acid, 15 drops in half a glass of water, three times a day. Within ten days she was practically well.

In reporting these cases of icterus, one simple and two malignant in form, I have not attempted to present anything new, but the disease being of such rare occurrence, and one of the patients suffering from a malignant attack having recovered, I have thought the report of enough interest to serve to refresh our minds in regard to this rare yet dangerous complication of pregnancy.

CLINICAL MEMORANDA.

CLINICAL NOTES FROM THE U. S. GENERAL HOSPITAL, FORT MONROE, VA.

BY DONALD MACLEAN, M.D., LL.D.,
MAJOR AND CHIEF SURGEON OF DIVISION, U. S. V.

IN a brief communication to the MEDICAL NEWS published July 30, 1898, in reference to affairs at this hospital, I promised information as to the result of the case of subclavian aneurism produced by a Mauser bullet. The patient suffered severely and grew gradually weaker. His father, a most intelligent man, came here from Tennessee and I took the utmost care to explain to both him and his son the true state of the case, namely, that the only chance for relief consisted in an operation, which held out a very slim chance of success, but *the only one*. I left the decision to themselves and before long the father came to me with the statement that both he and his unfortunate boy had decided to accept the chance of operation, which they had been frankly informed was a desperate one. Consequently I operated next day with the forlorn hope that the wounded artery might be the left carotid and the wound within reach of surgical treatment. The heroic father stood by my side and took in the whole procedure. My object was to secure the artery before the patient bled to death. This proved to be impossible and the poor boy bled to death on the table. The afflicted father, who witnessed the whole terrible and shocking scene, expressed himself as perfectly satisfied with our loyal efforts to save his boy and uncomplainingly accepted the melancholy result. Not only so but he most readily consented to any examination of the body which we wished to make.

We found, first, a long, irregular wound of the left subclavian extending almost to its origin. Second, a fracture of the transverse processes of the sixth and seventh cervical vertebræ. Third, fracture of the first rib. Fourth, fracture of the body of the scapula, through which the Mauser bullet had passed on its course to the surface. Notwithstanding the tragical nature and result of our efforts to save the life of this youthful hero we fail to discover any reasonable grounds for personal reflection or surgical condemnation. It was the only chance and we did all that could be done.

My friend, Dr. W. P. Chamberlain, First Lieutenant and Assistant-Surgeon, U. S. A., has kindly furnished me with notes of the following cases to be used as I think best:

H. S. H., aged twenty-eight years, private, Co. C, 22d U. S. Infantry, on July 17th, stated that he strained his back in January, 1898. Pain at times ever since, with attacks of fever and chills, the last one occurring July 4th. Sent to this hospital from Siboney on transport "Breakwater" July 19th. Forenoon, back better; slightly feverish. Afternoon, pulse 90; temperature 105° F.; pain in the back and legs much worse. No nausea; no epistaxis. Physical examination negative. July 20th: Feels better. Temperature, 102° F. July 21st: Pain in back and legs worse, otherwise about the same. Vomited his medicine (quinin); pulse, 80; temperature, 104° F. at night. Physical examination, negative, except slight enlargement of the spleen. Urine contains distinct trace of albumin. Patient was placed in a separate ward as a suspected case of yellow fever. July 22d: Less severe pain in back and legs; bowels moved with mild cathartic. Temperature, 102.8° F.; pulse, 88; respiration, 40. More albumin in the urine. Isolated with immune nurse. July 25th: Suspicion of yellow fever changed to typhoid and he was returned to his original ward under charge of Dr. Chamberlain. He suffered from slight cough and occasional subsultus. Abdomen tympanitic and covered with an abundant crop of characteristic rose-colored spots. Fever continued high till August 4th and then gradually declined, reaching normal August 10th, where it remained. The rose spots remained till August 3d. The bowels continued constipated, the pain in back and legs severe. There was retention of urine, necessitating the use of the catheter, and the pulse became very weak at times. The treatment consisted mainly in cold baths, whisky, milk diet, and daily enemata. Since August 13th he has been on light diet and in a wheel-chair, and is now convalescent.

This case is interesting from numerous points of view, but especially because of the sudden onset, the high fever with pulse not correspondingly high, the severe pain in the back and legs, and the albuminous urine, all of which, taken together, strongly suggested yellow fever in the case of a patient coming from an infected port.

Eleven men were afflicted with sunstroke, occurring in the vicinity of Santiago, except one, which occurred in Charleston. All were attended by loss of consciousness for periods ranging from five minutes to three hours in length. On recovery of consciousness all were suffering from severe headache, usually frontal and throbbing in character, except in the last case, in which the patient complained of a great feeling of pressure over the vertex.

About half the men complained of fever and nausea after becoming conscious and about the same proportion had visual troubles, usually darkening of vision or seeing streaks in the air. All had vertigo and ringing in the ears. Very severe headache lasted for periods varying in length from five to eighteen days. One month after the sunstroke about half the men were free from headache if in the shade, but all had severe headache come on upon exposure to the sun, in most cases associated with nausea and vertigo. Several of the patients were very nervous and were troubled with insomnia. Only one showed any mental change. His chief complaint was that his head felt "funny." He wore a startled, somewhat wild expression, and at times talked as if insane.

Injuries to Skull or Its Contents.—The following cases are of interest to compare with those of sunstroke:

B. S. H., aged twenty-four years, private, Co. F, 16th U. S. Infantry. Superficial perforating Mauser-bullet wound of scalp one inch above and behind the left ear. Track one and one-half inches long. Exit and entrance one-fourth inch in diameter and healed when first seen. Slight induration of track. No depression of skull. Occurred July 1st near El Caney. Patient lost consciousness for one-half hour and on recovering was bewildered, dizzy, and had severe frontal headache for eighteen days. Now (August 3d) is troubled with insomnia and slight vertigo on exposure to sun. Hearing normal in both ears. Thinks vision not quite as good as formerly in left eye. Has very slight ptosis of left upper lid.

W. P. H., aged twenty-eight years, private, Co. G, 12th U. S. Infantry. On July 1st a shell exploded within a few feet of him and he lost consciousness during half an hour. On coming to, blood was running from his nose, and on the following day he spat blood. Cough and spitting of blood at times ever since. Examination of throat and chest negative. Ever since has been extremely nervous and has a marked tremor of hands and limbs. Has ringing in ears, vertigo, and headache at times, aggravated or brought on by exposure to sun. Vision and hearing normal.

H. J., aged forty-two years, private, Co. F, 10th U. S. Cavalry. On July 1st shell exploded near him causing loss of consciousness for two hours. On coming to had severe headache and was deaf. Blood flowed from left ear. No epistaxis; no vomiting; no trouble with vision. August 2d: Has had dull, throbbing pain nearly ever since accident, confined to the left side of the head, running from occiput to external auditory meatus. Headache much worse on exposure to the sun. Hearing is much impaired in right ear and almost entirely destroyed in left. Little improvement in hearing or headache since arrival here.

K. B., aged twenty-one years, private, Co. I, 3d Kentucky Volunteers. Mother and father died of consumption. A brother and sister have cough and are called "scrofulous." Three brothers well. Three sisters and one brother dead, cause unknown. Never sick till present time. May 1st took cold, coughed, and was feverish for a week. Pain in left chest. Cough ever since. Has been on duty all the time but breath has been short. Dyspnea and cough on lying on right side. No fever. No chills. Measles began one week ago and entered hospital for that disease. August 15th rash of measles on face and chest. Much conjunctivitis. Brown coat on tongue. Left side of chest more prominent than right and moves less on respiration. Apex-beat of heart two inches to right of sternum. Percussion-note everywhere flat over left chest. Treube's semilunar space obliterated. Cardiac dulness two inches to right of sternum. Auscultation shows absent voice-sounds, diminished vocal resonance and tactile fremitus on left side. Respiration exaggerated on right. Cardiac sounds clear. Abdomen negative. Urine normal. Aspirated and one and one-half pints of creamy pus drawn off. After this operation cardiac dulness one inch to right of sternum. No resonance above left clavicle or scapula. Pus creamy and no odor. After being stained it showed decomposed pus-corpuscles and a few oval organisms in pairs. An agar-culture after twenty-four hours showed an abundant growth of oval organisms in pairs (diplobacillus) and a few large bacilli (probably a contamination).

August 16th: Under chloroform anesthesia an incision was made down to the seventh rib in the posterior axillary line, three and a half inches of the rib resected, about two quarts of pus evacuated, and a large double drainage-tube inserted. Six hours later the patient was perfectly comfortable. Cardiac dulness to right of sternum has disappeared; has continued to make rapid improvement, and appears to be thoroughly convalescent.

CALCULUS PYELITIS WITH PERINEPHRITIC ABSCESS. NEPHROTOMY; DEATH AFTER TWENTY-SEVEN HOURS

BY H. H. STONER, M.D.,
OF ROCK RAPIDS, IOWA.

MRS. H., aged twenty-seven years, married, of spare physique, had suffered during five or six years from vague pains in the abdominal region. Several times in the early history of the case she suffered from severe colicky pain, which was not diagnosed, or relieved by remedial measures. From the beginning of her ailment until June 1, 1898, she continued to perform her duties as housewife, the last two years of which were arduous. At this date she began to suffer from irregular fever, followed by profuse sweating but no rigors. Her temperature would sometimes rise to 103° F. during the afternoon, dropping to normal the next morning. At about this time she observed a tumor in the right hypochondrium.

The case came under my observation on August 6, 1898. Her family history was negative. The following condition was noted: She was weak and anemic; the heart beat was 116 to 124 per minute, and her afternoon temperature varied between 101° and 102.8° F. She also had profuse night-sweats. The facies portrayed unmistakably the presence of septic absorption. There was a sensitive tumor, about as large as a child's head, occupying the right hypochondrium two inches to the right of the umbilicus and two and one-half inches below the right

costal border. Percussion elicited dulness over the whole area of the tumor. There was a marked line of resonance between the tumor and ribs, which eliminated the possibility of it being connected with the liver. It moved with the diaphragm during respiration, although it was but slightly movable on palpation. There was an area of dulness on percussion in the right lumbar region, extending from the eleventh rib to the ilium and from the median line half way to the axillary line. An impulse applied to the loin was conveyed to the tumor in front. The urine was scanty, being about 16 ounces in 24 hours. It was highly acid, its specific gravity was 1030, and it was loaded with pus.

The diagnosis lay between tuberculosis of the kidney and renal calculus with pyelitis. That she was suffering from pyemia connected with a suppurative condition of the right kidney was evident. As an operation offered the only hope of relief, it was proposed and accepted. She was placed upon tonics for about ten days with the hope of improving her general condition, but without material success. She was, therefore, prepared for operation with the usual antiseptic precautions on August 20, 1898. She was placed in a semi-prone position with a sandbag placed beneath and pressing against the abdominal tumor. A transverse incision was made, beginning at the edge of the erector spinæ muscle, parallel with and one and one-half inches below the twelfth rib, which was supplemented by a longitudinal incision beginning at the lumbar end of the transverse one and continuing parallel with the erector spinæ muscle to the twelfth rib. This gave ample room for inspection of the deeper parts. The peritoneum was exposed in the outer extremity of the transverse incision. This was isolated with gauze, and a perinephritic abscess evacuated of about ten ounces of pus. The tumor proved to be the dilated right kidney which was tense and gave a vague sense of fluctuation. An aspirating needle was passed into the posterior surface of the kidney in the direction of the pelvis, and after traversing half an inch of kidney substance passed into a cavity from which thick, foul-smelling pus was aspirated. Upon manipulation within the pus-cavity the point of the needle came upon a stone within the pelvis of the kidney. A slender-bladed knife was now passed alongside of the needle and the incision dilated with the finger. The amount of pus evacuated from the kidney was estimated at sixteen ounces. At the bottom of the cavity and within the dilated pelvis of the kidney were three calculi, aggregating in weight 130 grains. The two smaller were easily extracted with forceps, but the largest, weighing 90 grains was embedded in the calices of the kidney and was removed with much difficulty. Owing to the adhesions and enlargement of the kidney it was thought best to establish drainage with a view of doing a nephrectomy later, if it became necessary. Therefore, after thorough irrigation with 1 to 5000 bichlorid solution, a rubber drainage-tube was placed in the bottom of the perinephritic abscess-sac, and a larger sized tube placed in the kidney cavity, and the wound closed.

During the operation the patient was twice given one and one-half pints of normal salt solution by subcutaneous injection. She was placed in bed in fairly good condition. Immediately after the operation urine began to escape from the affected kidney and continued to do so until 11 P.M., ten hours after the operation, when the patient began to suffer severely from shock, and the kidney ceased to perform its function. From this time on, in spite of stimulation, subcutaneous injections, external heat, etc., shock became more profound until she died, at 3 P.M., August 21st.

Except in cases of solid tumors of the kidney, and occasionally hydronephrosis, tumors of the kidney sufficiently large to be palpable through the abdominal parietes are seldom encountered. Sarcoma frequently produces a tumor whose manifestations are almost wholly confined to the abdominal region. Hydronephrosis sometimes assumes a degree of magnitude sufficient to distend the abdomen. For a purely pyemic process the size of this tumor is certainly interesting. Calculus pyelitis seems to have a peculiar predilection for the female sex, and an explanation of this may be found in the mobility of the uterus which, by its intimate connection with the bladder produces intermittent traction on the uterus, which by inducing a certain amount of inflammation in the pelvis of the kidney causes a secretion of mucus, by which a few crystals of the solids of the urine are cemented together, and the nucleus thereby formed for a future calculus. Or pregnancy, by pressure of the gravid uterus upon the ureters, may interfere with the flow of urine and induce hydronephrosis, which condition would be favorable to the development of renal calculus.

While it is true that many patients with nephrolithiasis go through the course of the disease with little suffering, yet this patient, except during the incipiency of the case, was more than ordinarily free from pain. She carried a stone in the kidney five or six years, a greater portion of which time she had pyuria, but not until septic absorption became pronounced did she awake to the fact that there was something radically wrong, and set about seeking relief from her condition.

MEDICAL PROGRESS.

The Disposition to Hernia and the Treatment of It.—KOCHER (*Correspondenz-Bl. f. Schweiz. Aerzte*, June 15, 1898) says that the disposition to hernia, about which opinions still differ so widely, is the most important point in the whole subject. Some writers claim that whoever develops a hernia must have had a previously formed peritoneal pouch in that situation, which by repeated pressure is gradually converted into a hernial sac; others are content to say that there was a congenital weakness of the fibrous layers, but no preformed peritonitic pouch, and yet others assert that every hernia develops in a well-formed congenital hernial sac, and that at the time of its occurrence some portion of the abdominal contents pass into the sac, thus separating the walls which before lay close upon one another.

That an anatomical disposition to hernia exists in many persons is shown by the fact that even in adults there is

often found in the inguinal canal and elsewhere such a peritoneal pouch as is above referred to, but which, except for some accident, remains empty; this is, however, not a hernia, any more than an adipocele in the inguinal canal is a hernia, though they both favor the development of one. It is often advantageous, now that the mortality from operation for rupture is so slight, to suture at the time of operation for inguinal hernia a weak inguinal canal, if such exists, on the opposite side to the already developed hernia. Such a disposition to hernia is manifested by a pouching forward of the canal upon coughing. The form of such a pouch is usually oval. Direct observation in such cases has shown that the disposition to hernia does not show itself, as was formerly stated, in the form of a small sac gradually pushing its way down the canal; but, that by the abdominal pressure, the peritoneum is pushed over Poupart's ligament in a rounded oval or conical process. The transversalis fascia remains at the internal abdominal ring, and the deep muscular layers are pressed apart to afford room for exit. The internal ring is also enlarged laterally, the epigastric vessels and the ascending ligamentous fibers being stretched and pushed toward the median line. The anterior wall of the canal is naturally stretched, and its fibers more or less separated. If the resistance offered by the external ring is greater than that of the canal itself, an interstitial hernia results. This is quite different from a properitoneal hernia, one which lies between the parietal peritoneum and the posterior surface of the abdominal wall.

While it is beyond a doubt true that a congenital hernia is due to the insufficient closure of the neck of the vaginal process of the peritoneum, one errs in attributing all herniæ to this anomaly. A congenital hernia can be recognized at operation by the fact that the testicle lies in the hernial sac, or that a combination exists with hydrocele of the cord, or that from the lower end of a closed hernial sac there extends along the cord a process reaching down to the tunica vaginalis containing often one or more cysts.

At operation it should be the aim of the surgeon to cure not only the hernia, but the disposition to the same, which according to Wood is a congenital sac in about one-third of the cases; and according to Roser is an adipocele in a large proportion of cases; and according to Berger is often a congenital weakness of the wall. Hence, his term "*hernie de faiblesse.*" In almost every instance there will be found to exist one of these three conditions.

For a fully developed hernia, Kocher considers his own operation the simplest and most satisfactory in its results; while for conical peritoneal pouches he advocates Bassini's method of treatment.

THERAPEUTIC NOTES.

Keloid and Intractable Inflammatory Patches Cured by Scarification.—LAWRENCE (*Brit. Med. Jour.*, July 16, 1898) twice excised a keloid of the right forearm of a man aged forty-six years. Each time it recurred as large and as painful as before. Though not at all confident of success, he was led by the discomfort which the growth caused the patient to make a further attempt to cure the trouble. With a five-bladed scarifier, the blades being one-twentieth of an inch apart, he made criss-cross incisions into the keloid and surrounding skin until the whole area was thoroughly cut up into squares, 400 of them to the square inch. Bleeding was encouraged by the application of hot boracic-acid dressings, and later the wounded area was dusted with iodoform and dressed with zinc-glycogelatine, and a piece of rubber tubing four inches long and three inches in diameter was applied to give continuous pressure. This was held firmly in place by strips of plaster, which did not entirely surround the arm, and thus did not interfere with the venous return. The dressings were twice changed at intervals of two days, and pressure with the rubber-pad was kept up for several months. During this whole period the scar was thin and pliable, and gave no pain. The pressure was then discontinued. Six months later the cure was still as complete as ever.

The same method of treatment has been employed with success by the writer in chronic patches of eczema, edematous lupus erythematosus, chronic patches of non-apparent catarrhal inflammation of the skin, with marked irritation as left after a general eczema, patches of chronic traumatic dermatitis, and intractable patches of chronic lichen planus. The incisions in these cases should be superficially made, and the blades of the instrument in all instances should be at least one-sixteenth of an inch apart, otherwise there is danger that some of the squares of skin will be torn away.

Salicylate of Nicotin for Scabies.—WOLTERS (*Rev. de Therap.*, September 15, 1898) recommends the use of salicylate of nicotin in the treatment of scabies. The drug occurs in fine white crystals readily soluble in water. These are ground and made into an ointment containing $\frac{1}{10}$ per cent. of the active principle. Lanolin makes a good base to the ointment. Of sixty-seven patients upon whom this treatment was tried sixty-four were cured by a single application. The remaining three were greatly improved, but it required several applications of the salve to destroy utterly all the parasites. Three patients returned after a certain time complaining of a recurrence of the disease but investigation showed that there had been reinfection from an external source. This ointment was most agreeable to the patients, being invisible, odorless, and unirritating. There were no symptoms of intoxication in any instance.

Vasogen as a Vehicle for Iodin.—FRIEDLAENDER states that iodin is rapidly absorbed through the skin and mucous membranes when it is mixed with vasogen (oxy-vaselin). It is used in the strength of 6, 10, or 20 per cent. of iodin, generally 6 per cent. Its use is advised for various ills, such as sciatica and intercostal neuralgia, ulcer of the leg, enlarged glands, blenorrhagia, epididymitis, and in gynecology for cervical ulcer, and parametritis.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

AND NOS. 706, 708 & 710 SANSOM ST., PHILADELPHIA.

SATURDAY, NOVEMBER 12, 1898.

THE visit of Mr. William Antivaccinationist Tebb to this country should not be allowed to pass unnoticed, particularly as he is here to propagate the antivaccination craze. We have no doubt that if he expends one-half the energy and money here which he and his deluded fellow-workers have spent in England, such outlay will be rewarded by a considerable following, particularly if he operates in the hysterogenic zones of eastern New England, and in those portions of Canada in which mental compulsions and obsessions are endemic. The annals of spiritualism, faith cure, Christian science, osteopathy, and antivivisection, not to speak of the innumerable religious and mystic cults and other psychoses that have taken root here during the past half century, portend a warm reception to any fad, particularly if its understanding surpasses reason, common sense, and science.

Mr. Tebbs believes it to be his mission to start na agitation in this country against regulations of health boards which make it necessary for children to be vaccinated before they can enter the public schools, and also against the Federal law requiring all immigrants to be vaccinated. Furthermore, he plans to hold the next International Antivaccination Congress here, the object being to enlighten the public concerning the evils of vaccination. Mr. Tebbs avers that he has in his possession pictorial proof that the health of some immigrants has been injured by vaccination. Poor immigrants! Poor Mr. Tebb! We commiserate you, Mr. Tebb, and trust that the burden of these proofs is not greater than you can bear. We must inform you, however, that deeply rooted in the minds of the American people is a conviction which reads: "You can fool some of the people all the time, and all of the people some of the time, but you can't fool all the people all the time."

DR. STUART TIDEY of London, in a letter to the *British Medical Journal*, October 22d, describing a visit to the Hospital of San Giovanni, at Turin, Italy, says: "What I wish most to record was the discovery there, worked out in the concrete form of mechanical and physical contrivance, of a method of treatment which I had hitherto believed was especially my own. On entering the laboratory I saw an apparatus for the preparation of some gas, and on asking the professor (Carlo Forlanini) its use, he said: 'It is for the evolution of nitrogen to inject into the pleural cavity and compress the pulmonary parenchyma in unilateral tubercle of the lung.' 'What results have you obtained?' I asked. 'They all get well,' he replied. I then asked the professor if he knew that his method was being practised in America. 'No,' he replied, 'I have practised it for ten years and they must have gotten it from me.' He told me further that when the diseased portion of lung had healed the healthy portion expanded and reoccupied the space from which the nitrogen gradually disappeared." It thus would appear that Murphy's injections into the pleural cavity had been anticipated.

EVADERS of the law are notoriously fertile in resources which save them from its grasp. Oftentimes they are so clever that despite the perniciousness and iniquity of their purpose their shifts compel a sense of admiration. We are prompted to these remarks by the receipt of a sheet bearing the pretentious title "United States Health Reports," and the subtitle "The American Authority on Matters of

Health, Sanitation, and Hygiene," stamped on a streaming banner clutched in the mouth of an American eagle, which is perched on a staff flying the American flag; all of which gives the sheet an appearance of authenticity and officialness, qualities which, no doubt, the perpetrators of the reports would have the unsuspecting reader believe it possesses. The leading article is entitled "A Model Home for Invalids," and as this was blue-penciled it was evidently intended that it should attract attention. We are glad to be able to meet half way in this respect its author, one Alonzo B. Carrier, M.D., a name unknown to us, and we venture to think also to fame.

. . . . . .

The author introduces his subject by the very questionable statement that "In the treatment of diseases peculiar to woman, including the usual accompanying nervous manifestations, very much depends upon the environments of the patient." There is more in that simple statement, however, than a person who does not read further would suspect. The writer then goes on to say that for the protection of his readers and patrons who recognize his sheet as the American authority in all matters relating to health—God save the mark—that in response to inquiries concerning the general reputation and character of an institution conducted by Dr. ———, No. —— ——— street, and the advantages claimed for his home for women ill or *in trouble*, he decided to investigate it. Dr. ———, he states, is so thorough in his practice that he has become indispensable to his professional brethren, who frequently avail themselves of his services in delicate cases. Moreover, "Dr. ——— gives personal attention regarding any trouble ladies find themselves in, and insures absolute privacy, *a minimum amount of risk, with maximum benefit.*" Alonzo B. Carrier, M.D., then draws his eulogistic article to a close, but not without saying that appointments can be made by letter or in person with Dr. ———, and that he cordially extends to Dr. ———'s home and method of treatment the unqualified editorial and official endorsement of the "United States Health Reports."

. . . . . .

Although we have no fear that any reader of the "United States Health Reports" will not fully understand the purport of Dr. ———'s home and the endorsement of his method of treatment by Alonzo B. Carrier, M.D., we, nevertheless, feel it a duty to ourselves and to our readers to say a word concerning Dr. ———, whose advertisement may be found in all the daily papers, and who is already well known in the police annals of this city. About eight years ago a young man of respectable appearance, a graduate of the Hahnemann Medical College of Chicago, and a son of a reputable clergyman, came to this city and opened an office in Lexington avenue. He made a few professional acquaintances, but depended for a clientele upon a card which he had inserted in all the daily papers, calling attention in an insinuating way to the success which he had "in getting ladies out of trouble." His business was soon very lucrative, apparently, for his horses and carriages were numerous, and every day he was to be seen constituting a conspicuous member of the fashionable throng that makes the east drive in Central Park its own, from three to five in the afternoon. Not content, however, with making such vulgar display of ill-gotten wealth, he must needs remove to a fashionable part of the city. That he might be within reach of the then most potent limb of the law, he leased a mansion next door but one to that of Inspector Byrnes.

. . . . . .

The longest lane eventually has a turning. One morning the daily press announced the fact that a young girl had died from the results of a criminal abortion, and on her death-bed she swore that Dr. ———, whose house and methods are now receiving the endorsement of the "United States Health Reports," had performed a criminal operation upon her. He was arrested, locked up, and eventually released under heavy bonds. The day of his release was the day of his disappearance. He fled, at least let us hope that he fled, and nothing more was heard of the matter for about two years. In the interval the city government underwent something akin to a revolution. The district-attorney's office was rehabilitated. Many indictments had been mislaid or were quashed, or something had transpired to make them no longer operative. And the quack came back.

. . . . . .

This may or may not be at the present time a

wide-open town, but it depends entirely upon the interpretation put upon these words which have now come to have a very expressive meaning, whether or not it deserves to be so called. We venture no opinion. Despite this, however, it seems to us that we have called attention to one of the most nefarious, loathsome, abominable, and abhorrent advertisements that can possibly exist. Not content with advertising in the daily press in such an insinuating way that even a terminal dement would understand the purport of his words, here is an individual who, despite the fact that he has already been within the clutches of the law, is yet parading his infamy before the public under the guise of what he would have us believe is a legitimate journal established for legimate purposes. We particularly call the attention of the County Medical Society to this man and his advertisements, and at the same time say to Alonzo B. Carrier, M.D., that he is either an accomplice or a stool-pigeon who is so highly perched on a pedestal of infamy that he will find great trouble in coming down even with assistance.

THE recent episode at Vienna brings bubonic plague into prominence once more and renews interest in the fact that it is still epidemic at and around Bombay. This would seem to indicate that the much-talked-of inoculations had been a failure, yet such does not appear to be the case. According to the *Times of India*, the experience with protective inoculations at Hubli is most satisfactory. The district contains 40,000 people, of whom about 35,000 have been inoculated to date.

By far the great majority of the cases of plague that have occurred have been among the uninoculated, despite their disparity in numbers to those inoculated. During the first week of September among 32,000 inoculated there had been but 69 cases of plague reported, while among 8000 uninoculated there were 417 cases. An ungrounded fear of the results of inoculation, a distrust of the foreign Christian medical men, that instinct of opposition to government which characterizes the lower classes in all countries and finally, and most important, religious scruples in the matter have prevented that universal application of inocultaions in any one district that might furnish a striking proof of their protective power. We cannot help noting here in passing that the British government is having a serious time of it regarding religious or conscientious scruples in the matter of the effort to protect her people against the ravages of contagious disease. While in India religious objections stand in the way of inoculations against plague, in England itself conscientious scruples are now an all-sufficient reason for the avoidance of the vaccination law. Verily, conscience seems to masquerade at both ends of the Empire under a mantle whose folds hang strangely like those which have clothed ignorant, obstinate superstition in all ages and climes. For this sort of thing in matters where public health is at stake, there should be no squeamish consideration dictated by a false conservatism and an undue regard for personal liberty and so-called religious prejudice.

FRACTURE OF THE SPINE.

AT the present day there is a growing tendency, based upon the successful results that have followed operative procedure in suitable cases, to operate in cases of fracture of the spine. Moreover, the class of suitable cases has been much widened by recent experience along this line, so that it includes most of the fracture-dislocations, the fractures of the neural arch, hemorrhage, and secondary inflammatory exudate. Outside of this class there must remain the severer injuries to the cord from overflexion and direct crushing by bone, in which total paralysis is instantaneous and complete division of the cord is the only explicable lesion. Operative interference will meet with most success in those cases in which the injuries involve the lumbar or lower dorsal region, and in which the operation of laminectomy is done immediately. Operative experience, furthermore, has demonstrated fully that cord degenerations from a continued pressure are rapid and that the higher the injury and the seat of operation the greater the danger.

The difficulties and the uncertainties of diagnosis are many. The considerations presented to the surgeon by such a patient are, first, the symptoms of the fracture of bone, crepitus, undue mobility, localized pain, loss of function and deformity, and secondly, the symptoms of paralysis. Any surgeon with experience knows that he is doing his patient the greatest possible harm if he attempts to elicit the crepitus or the undue mobility. He knows that lo-

calized pain and loss of function may follow a mere sprain; and it is a fact that some of those cases which show almost no deformity are the, now frequently recognized, fractures of the laminæ which give best results from operative interference. Nor is he given great assistance in his decision by the nerve symptoms, in view of the fact that the cord of an animal may be repaired after total division and certainly that of a man after hemisection. Furthermore, there are many reported cases where entire recovery or improvement has followed severe injuries to the spinal cord itself.

These points must lead to uncertainty as to the exact lesion present and in the light of the lessened danger from the operation, and the recent observations regarding the frequency of fracture of the neural arch there seems a justification for an exploratory operation in many of the cases. The experience of operators up to the present time has demonstrated beyond doubt that serious hemorrhage from the operation is not to be feared, that the loss of cerebrospinal fluid is without consequence, and that the removal of the spinous processes and laminæ from a number of vertebræ does not materially weaken the stability of the vertebral column. Some subjects improve rapidly and are cured, in others the improvement is slow and never complete, while some show no improvement whatsoever. Yet even a small percentage of cures or even of improvement is a sufficient justification for the operation, when a condition of actual pressure is relieved thereby; and this probability must be placed against a certainty that no improvement can follow a policy of non-interference. This probability of improvement gains force from the uncertainty that must always exist as to the extent of cord injury, and from the amount of repair that sometimes does follow a prompt removal of pressure. There are very few surgeons who would not advocate operation in a depressed fracture of the skull with cerebral symptoms. The indications for the operation under discussion must be the relief of pressure from bony parts, the evacuation of blood-clots causing pressure, the arrest of hemorrhage, and the correction of the deformity of the spine. The chief and practically the only indication is, in reality, the relief of pressure on the cord, to favor a re-establishment of function, and oppose secondary ascending degeneration.

As previously stated these remarks apply, more especially, to the lumbar and dorsal injuries, but there is no reason aside from the increased danger of operation why the same procedure may not be adopted in cervical fracture. The cervical region seems the one to which extension and manipulation is best adapted, yet this procedure possesses a forbidding danger to the patient from a possible sudden death during the manipulation. One reason for infrequent operation in former days was the conclusion that the crushing injury to the cord was in most instances caused by the sharp upper border of the body of the lower vertebra. Facts opposed to this are a displacement, less extreme, in most cases, than was formerly supposed; the frequency of the fracture of the laminæ as a pressure and destructive cause; and that the removal of a lamina in a marked displacement has been followed by improvement.

ECHOES AND NEWS.

The American Medico-Psychological Association.—The annual meeting of this society will be held in the city of New York on Tuesday, Wednesday, Thursday, and Friday, May 23 to 26, 1899. C. B. Burr, secretary.

Professor Braun's Twenty-fifth Anniversary.—An ovation was tendered October 14th to Professor Braun, the director of the Obstetric Clinic in the General Hospital, Vienna, on the twenty-fifth anniversary of his occupation of the position.

Sickness in the Camps.—At the hearing before the subcommittee of the War Investigation Commission at Harrisburg, Pa., it was claimed that the sickness among the soldiers was caused chiefly by the dainties which their relatives and friends sent them.

Spanish Soldiers Home.—The steamer "Montserrat," with 1788 troops from Cuba on board, arrived at Cadiz, Spain, November 2d. There were ninety-seven deaths on the voyage. Eight hundred of the soldiers were sick, and many of them in a dying condition.

A Plucky Doctor.—Dr. Trevor, the ship surgeon of the ill-fated "Mohegan" that recently struck on the "Manacles" off the south coast of England, escaped with his life but was rescued only after he had clung to the masthead of the vessel for about seven hours.

Professor Stricker's Successor.—Professor Phillip Knoll, the Professor of Experimental Pathology at the German University of Prague, is to succeed to the Chair of Experimental Pathology at the University of Vienna made vavant by the death of Professor Stricker last year.

Yellow-Fever Hospital at Santiago Closed.—The last and only remaining case of yellow fever in the yellow-fever

hospital at Santiago was discharged cured November 2d, and the hospital was closed. The total sick at Santiago November 4th numbered 1113; fever cases of all kinds, 613.

Death of Doctor O'Flanagan.—Dr. O'Flanagan, the author of a book called "Medical Men and Manners of the Nineteenth Century," which created quite a sensation in English medical circles some twenty years ago, died recently at Houghton-le-Spring, Durham, England, from meningitis.

The Fordyce Barker Memorial Bed.—Mrs. Elizabeth Lee Barker has given by will to St. Luke's Hospital, New York, $5000 in perpetuity as a memorial to her late husband and their son, to be used for founding and supporting a memorial bed in the hospital, to be known as the Fordyce Barker Memorial Bed.

Guarding against the Bubonic Plague in Asia.—The commission charged with the duty of taking precautionary measures against the bubonic plague has engaged a staff of forty doctors, who will proceed immediately to Samarcand, Turkistan, where, as stated last week, there has been quite an invasion of the disease.

The Influence of Character and Right Judgment in Medicine.—Sir Dyce Duckworth, in an address with the above title, relates that Matthew Beattie once observed: "I am persuaded that the most successful treatment of patients will depend upon the exertion of sagacity, or good common sense, guided by a competent professional knowledge; and not by following strictly the rules of practice laid down in books even by men of the greatest talents and experience."

An Extra-State Consultant for a New York State Institution.—The announcement is made of the appointment of a Philadelphia ophthalmologist as consultant to Craig Colony for Epileptics, situated at Sonca, New York. Have we perhaps no New York ophthalmologists capable of filling the position, or is there some other equally good reason for going out of the State to find a consultant for what is practically a State institution?

The New Royal Member of the Profession.—Marie, the young Queen of Portugal, who has been known for some time to be engaged in the serious study of medicine, is now reported to have received her formal degree of doctor of medicine. Rumor adds that her first patient is her husband, whom she is treating for obesity, and that so far the new M.D. is satisfied with the results of the treatment. There would seem to be depths in connubial felicity, even beyond having to pass judgment upon the creations of a wifely dilettante in the culinary art.

Health of the Philippine Army.—The climatic conditions at Manila are changing for the better, and it is hoped that the advent of the dry season which is approaching will see a great improvement in the health of the troops. The surgeons' returns show about 1800 men on the sick-list, and the weekly mortality for the past month has averaged about eleven. General Otis has issued a general order permitting the surgeons in charge of regiments or independent battalions to spend 30 cents per day for delicacies for each man on the sick-list. This will probably result in a reduction in the number of sick.

The Dress of Women Students of Medicine in St. Petersburg.—It would appear from an edict recently issued in St. Petersburg that the women students of medicine will hereafter be required to wear a distinctive dress. When they assembled at the beginning of the autumn session they found a notice conspicuously posted in the classrooms not only prescribing the color and cut of the dress, but also enjoining the purchase of the material at a particular establishment and the making of the garment at a specified place. This edict appears to have issued from the police instead of from the Education office.

"Posed as a Doctor to Wed a Pretty Girl:" This is the line-heading of a pathetic story in one of the daily papers. The wooer won and wed the maid. After marriage everything went on happily until the bride learned her husband was really not a doctor. Then life was *not* "all one grand sweet song"; in short a separation resulted. He may have been a good husband in other respects; but he was not what she had married him for—a doctor. The story further tells that this pseudo-doctor "had money." Who could blame the young lady? Beats there the feminine heart which would not succumb to a combination so rare as a doctor with money.

Berlin Aroused about the Plague.—There has been considerable alarm in Berlin owing to the plague at Vienna, and the Government has deemed it necessary to allay popular anxiety by announcing that no experiments similar to those which led to the outbreak at Vienna are permitted in the Berlin laboratories. It is said, however, that private research for Asiatic cholera germs is proceeding in the laboratories of scientists like Professors Virchow, Leyden, Koch, and others, and the *Cologne Gazette* urges the Government, and justly, to take measures to prevent infection by requiring an official permit for such experiments, which, it is claimed, should be restricted to specially isolated buildings.

Smallpox in Cuba.—A report made to General Wood November 4th, by Captain R. S. Woodson, surgeon of the regular army, who accompanied Colonel Hood's six companies to Gibara, says there are more than 5000 cases of smallpox in Holguin and its vicinity, and several hundred at Gibara. The smallpox has continued uninterruptedly more than three years, the Spanish and Cuban authorities making little intelligent effort to overcome it. The form of the disease is most malignant and the recoveries few. The mortality is increased by the unhygienic modes of living. Captain Woodson advises sending no more troops till the epidemic is checked or the isolation of the sick accomplised. He established at Gibara a smallpox hospital with 150 beds, isolating 200 cases.

Sioux Indian Nurses.—At the Third Division hospital, Jacksonville, Fla., are a number of patients, who, when they are restored to health, can have the distinction of

saying that they have been nursed back to health and strength by the work of four sisters, who are direct descendents of some of the Sioux tribes of Indians of the Dakotas. These women are distinctively Americans and represent the entire order, of the Congregation of American Sisters, as it to-day exists in the United States. Only Indian girls are admissible to the ranks. The order volunteered to go to the front when the war broke out, with the end in view of following up the line of battle, and of taking care of the fallen and wounded on the battle-field, but it was only recently that their proffered services were accepted.

Treatment of the Insane in Persia. — An English missionary in Persia, in speaking of the backward condition of that land in nearly all directions of charitable and correctional effort on the part of the native population, says that there are no hospitals, no dispensaries, and no lunatic asylums. The harsh treatment of insane patients is thus described: "The dreaded lunatic is chained, his feet fastened in the stocks, is constantly beaten and half-starved, with the idea that if badly treated, the devil will the sooner leave him. And then, as a last resource, when the friends have grown tired of even this unkind care of their relative, the lunatic is given freedom in the desert. His hands are tied behind his back, and he is led out into the desert and is never heard of again. There are no homes for the blind and crippled, and none for the incurable in this land."

The Time When the Greatest Number of Deaths Occurs.— The time of day when the greatest number of deaths and births occur has been answered recently in the *British Medical Journal* by Professor Raseri, who has carefully investigated a large number of statistical reports for information bearing on the problem. With the statistics of 25,474 cases of death and 36,515 cases of birth, he has found that the maximum number of deaths occur between two and seven o'clock in the afternoon, while in the early hours of the morning there are the greatest number of births, and in the early afternoon the smallest number. The coincidence of the time of the maximum number of deaths with the hours when the pulse-rate and temperature are at their highest point in health, and when there is a febrile exacerbation in case of illness, has been offered as the explanation of this fact.

His Heart in His Boot.—In the *New York Medical Journal*, November 5, 1898, it is told how one of Sir Henry Ketchener's officers was shot above the left nipple and recovered from the wound. When his surgeon expressed wonder that the ball had not entered his heart he said it had not probably because his heart was in his boot at the time. This recalls a conversation which the writer had with Ex-Governor O'Farrell of Virginia, who, while a Confederate soldier in the Civil War, had been shot five times, and had received three sword wounds. One bullet entered just beneath the heart and came out at the back. Doctor Hunter McGuire attended him at the time. After the then Colonel O'Farrell's recovery, Doctor McGuire said he wondered how he had not been shot through the heart. The Colonel said it must have been because his heart "was in his mouth" at the time.

The New Army Hospital at Savannah.—Twenty-one acres of ground has been secured for the hospital at Savannah, Ga., and it is said that the establishment will cover the whole tract, and be the largest hospital maintained under the auspices of the Federal government. The ground plan of buildings will be rectangular, with covered ways connecting all of the buildings with each other, and with the administration building in the center of the group. There will be forty-nine buildings in all. The cost of the Savannah establishment is to be $150,000. The material used will probably be Georgia pine. The buildings are to be designed and constructed with a view to permanency. Each building will be ceiled inside and under the floors. Each of the four sides of the quadrangle will contain a ward capable of accommodating 250 single beds, with ample space between, making room for 1000 beds in all. One ward will be set aside for surgical cases, and an enclosed passage-way will connect it with a modern operating-room. Besides the general wards there will be private sick-rooms for the accommodation of invalid officers. The plumbing is to be of a permanent character, and the drain-pipes will be connected with the city sewer system. The artesian water-supply will be unlimited. The heating will be by means of coal base-burners. It has not been decided whether the lighting will be by electricity or gas, but both are immediately at hand. There is an ice factory within fifty yards of the site, and ice is 15 cents per hundred pounds by retail. The officers' quarters will be of two stories. The dormitories for the nurses and hospital corps will occupy two buildings. The chief surgeon will have a private residence.

Two Instances of Scientific Intuition.—One of the notes to Sir Dyce Duckworth's Harveian oration (as published in the *Lancet* October 22d) is of interest just now since the plague has come prominently before the public again: "Athanasius Kircher wrote in 1659, two years after Harvey's death, that 'the propagators of plague are little worms so small, fine, and delicate that they cannot be recognized by the senses.' It was left for the Japanese bacteriologist, Kitasato, to discover in 1893 the bacillus of plague." A passage quoted from Harvey's "Anatomical Exercise" (lvii) on the generation of animals affords an equally striking example of intuitive prevision on Harvey's part, respecting the reaction of the bodily tissues in inflammation. In it we have an anticipation of what is usually thought to be the most distinctly modern feature of the doctrine of inflammation. Referring to the effect of spider poison when introduced by a prick under the skin he wrote (translation ours): "The skin at once draws itself up into a prominence around the very spot where the puncture has been made and puts on, after a short time, the redness and heat of inflammation as if to gird itself for the combat and strengthen itself for the expulsion of the harmful agent." Sir Dyce Duckworth adds: "What have we here but a forecast of the modern researches of Metchnikoff and others upon the action of phagocytes in inflammatory foci? The idea

of a contest in the involved tissues was, I think, singularly prophetic of the histological discoveries to be made 230 years later and displays the intuition of Harvey in his study and interpretation of the secrets of Nature without any other aid than his simple vision."

SELECTION.

THE QUARANTINE STATION OF CAMARAN IN THE RED SEA.[1]

THE committee on construction of the lazaretto at Camaran reported the result of its labors on March 17, 1898, and later presented a supplementary report at the session of the council held August 20, 1898. The basis of the report was a statement drawn up by Engineer Roullet under direction of Dr. Stiepovich, secretary of the superior council of health, detailed for service at Camaran. This statement covered the work executed at Camaran up to May 25th of the current year. The work comprised six hospitals; 12 houses for persons of rank; 1 building for machinery, with 1 annex and accommodations for engineers, apparatus for distilling sea-water, ice-plant, steam saw, repairing-shop, etc.; 1 building for the accommodation of the personnel, officers, pharmacy, and for storage; 5 small houses for lodgings for guards; 1 water-tower with ice-house in its lower portion; 1 building to accommodate the steam plant, brick, tiles, plaster mill, and large storeroom; 8000 meters (about 6 miles) of railway laid; 2 cisterns cut in the rock and reservoirs with a capacity of more than 4000 tons; 2 conduits of fresh water which supply the cisterns; 1 conduit for supplying fresh water to vessels at the Mervani jetty; 1 conduit supplied from the wells on the main road, with cisterns and filters at the wells; 47 pavilions for latrines, with 24 sinks and 94 basins; 1 steam brick and tile plant with drying spaces; 1 plaster workshop with crusher; inclosed spaces for storage; lodgings for workmen.

The lazaretto of Camaran is arranged to receive 4000 pilgrims at one time, but the present buildings and those which it is proposed to erect will accommodate 6000. The following is a brief description of the work completed and in place:

1. A large structure which accommodates the inspector and physicians, and contains offices, a pharmacy, and a storeroom for supplies. It is a brick building on a stone foundation. On the ground floor are the offices, pharmacy, and supply department. Above, on the first floor, are the apartments of the inspector and the eight physicians, and the bathrooms. The building is surrounded by a veranda, forming a circular gallery 3 meters wide, on the ground floor and first story, and affording complete shelter from the sun. The plan of construction adopted secures perfect ventilation and prevents suffering from heat. To the northeast of the building is a pavilion containing latrines.

2. Five small brick buildings roofed with wood and tiles, each being 9 meters in length and 4 in width. Two of these buildings are used, one as a workshop for the manufacture of cement blocks, the other for the manufacture of sewer-pipes. The first contains a hydraulic press, the second molds and models for tubing.

3. Machine house. This building is 25 meters long by 20 wide and 12 high. It is constructed entirely of stone, the walls being 0.80 and 60 centimeters thick. The roof is iron, covered with brick. Ventilation is so carefully provided for that the temperature in the sections containing the distilling apparatus is lower than in the offices. On the south side of the building is an annex, 10 meters long by 7 wide, containing a "mirrless" generator, a forge, and a repair shop. The machines are installed on the ground floor of the building, and comprise a refrigerating-plant, pressure-pumps, condenser, receivers for fresh and sea water, for use in condensing sulphuric acid, apparatus for the distillation of sea water (yarrand), a De-Naeyer generator, a steam-engine of 40 horse-power, a pump for feeding the two water-receivers, and a steam saw. All the plant is worked by a transmitter set in motion by the motor attached to the ice-plant. The kitchen opens on a wide and airy corridor. On the east and west fronts is a veranda 2 meters wide. On an elevation of 5 meters on the north front is a magnetic filter, through which water passes to the conduits. In the courtyard of the machine-house is a small structure to receive kitchen refuse.

4. A stone building constructed on a small hill overlooking the machine-house and serving as a water-tower and ice-house. It contains 8 reservoirs of fresh water of 140 tons capacity and an ice-machine of 60 tons capacity. The building is 16 meters long by 10 wide and the walls are more than 3 feet thick. All the buildings at Camaran are whitewashed as a protection against contact with the air, which would otherwise disintegrate the brick and stone.

The delegate of England, Dr. E. D. Dickson, protested against the establishment of a bacteriological laboratory at Camaran, not only on account of the expense which it would entail, but because in the present state of our knowledge of bacteriology a laboratory of bacteriology would in many cases furnish diagnoses at variance with the clinical symptoms observed and thus embarrass the regular course of restrictive measures in force at the lazaretto.

[1] From advance sheets of the weekly report of the United States Marine Hospital Service. This quarantine station on the Red Sea in its completeness and substantial character might well be taken by our Government as a model for its quarantine establishments.

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

THE NATIONAL RELIEF COMMISSION—HOSPITAL NOTES—MEDICO-LEGAL SOCIETY—SEMICENTENNIAL OF BUCKS COUNTY MEDICAL SOCIETY—ABSCESS OF LIVER; GALL-STONES — PORRO'S OPERATION — OBITUARY—HEALTH STATISTICS.

PHILADELPHIA, November 7, 1898.

PRESIDENT Converse and Secretary French of the National Relief Commission are going to Washington for a conference with Secretary Alger as to the future work of

the commission, a feeling being prevalent that much of the work now being carried on by it properly belongs to the Government. The total contributions to date are $78,405.40 and supplies to the value of $40,345.00 with which a vast amount of good has been accomplished, supplies of all kinds being still forwarded to the camps even at this late date.

Hospital trains under various auspices continue to bring large numbers of sick soldiers to the city almost daily, but now that the Government is over its "rush" work, probably in the near future there will be a speedy diminution in the number of arrivals. An interesting phase of this hospital care of soldiers is the matter of compensation by the Government. As is well known compensation is to be made, but one of the hospitals most anxious for a large number of patients has been making, and with success, strenuous efforts to collect money from the public for this work. Right and left persons have been solicited and no efforts spared to induce them to help this charitable (?) work along. To the ordinary observer it seems a little queer to solicit help for the performance of work which is to be paid for by the Government and comments are freely made as to the impropriety, to say the least, of these methods.

The corner-stone of the Phœnixville Hospital, which has just been erected at a cost of $25,000, was laid Saturday afternoon; it is of brick and Indiana limestone, with marble trimmings, and three stories high. Dr. M. W. Snell is to be resident physician with Drs. Rhoads and J. Chalmers Da Costa of this city consulting surgeon.

At the quarterly meeting of the Medico-Legal Society the following officers were elected for the ensuing year: Dr. E. V. Wheeler, president; Dr. A. M. Eaton, first vice-president; Dr. L. H. Adler, second vice-president; Dr. S. M. D. Peltz, treasurer; Dr. C. H. Clewell, secretary; Dr. J. D. Nash, librarian.

The Bucks County Medical Society celebrates its fiftieth anniversary last Wednesday at Doylestown, many good papers being read and a jubilee being held in the evening. The following officers were elected: President, Dr. O. H. Fretz; vice-presidents, Drs. R. C. Faulke and A. S. Wilson; secretary, Dr. A. F. Myers; treasurer, Dr. Frank Swartzlander.

Among the interesting papers read before the Philadelphia County Medical Society, October 26th, was a report on some abdominal cases by Dr. Mordecai Price. The first case, "Abscess of Liver; Gall-stones," occurred in a patient with a tumor, the diagnosis of which was obscure. After an incision had been made, the kidney was found to be normal and the gall-bladder empty, but the liver, which extended to the brim of the pelvis, was full of pus as determined by the insertion of a small hypodermic needle. Twenty-four gall-stones were removed, their presence in the liver being due probably to an ulcerated, overdistended gall-bladder which had caused the abscess and as this abscess enlarged, the stones were gradually forced from the gall-bladder into the liver.

The second case was a "Porro Operation at Term" in which a large fibroid in the birth-canal complicated labor. Dr. Price is an enthusiastic advocate of Porro's operation, and, as in the case above, claims that both mother and child can be generally saved while Cæsarian section has a high mortality.

Dr. H. L. Williams reported to the Pathological Society two cases of "Accessory Thyroid at the Base of the Tongue," and Dr. Muehleck presented specimens of pyonephrosis from a case in which the clinical diagnosis had been typhoid, lobar pneumonia, and enlargement of the liver. Although Widal's reaction had been positive, the post-mortem showed no evidence of typhoid, nor was the liver enlarged.

Dr. Robert Lawry Sibbett died this week from paralysis at Fairfield. In 1873 the Medical Society of the State appointed him Chairman of the Committee on Medical Legislation, and to him is given much of the credit for the passage of the Registration Law. He was President of the Section on Obstetrics at the Ninth International Medical Congress, held at Washington in 1887.

The total number of deaths occurring in Philadelphia for the week ending November 5th, as reported at the Health Office, was 394, of which 82 occurred in children under 5 years of age. The total number of new cases of contagious diseases for the week was 280, reported as follows; Diphtheria, 89 cases, with 33 deaths; scarlet fever, 21 cases, with 2 deaths; typhoid fever, 170 cases, with 14 deaths.

MEDICAL MATTERS IN CINCINNATI.

[From a Special Correspondent.]

CASE REPORTS AT THE ACADEMY OF MEDICINE—THE NEW PRESBYTERIAN HOSPITAL—THE MIAMI VALLEY MEDICAL SOCIETY—GIFT TO THE CINCINNATI UNIVERSITY.

CINCINNATI, November 7, 1898.

THE meeting of the Academy of Medicine, October 31st, was devoted to case reports. Dr. C. R. Holmes presented a patient who had received a gunshot wound of the head. The ball had glanced from the orbital prominence, struck the sclera without lacerating it, and had lodged in the soft parts of the malar region. The internal structures of the eye were ruptured by transmitted force. Dr. Heidingsfeldt presented a patient with a birthmark who had been treated by the electric needle, and Dr. H. J. Whitacre a patient who had suffered from a ruptured middle meningeal artery, upon whom an operation had been performed.

Dr. C. A. L. Reed showed gall-stones from three recent cases. One collection contained 360 stones of uniform size and beautifully faceted. Another specimen had been removed from the common bile duct. The latter was of interest because of its unusual size. The stone was oval in shape and measured 2 cm. in its long diameter and 12 mm. in its short diameter. Dr. Edwin Rickets reported a case of pregnancy at term in a carcinomatous uterus, in which hysterectomy had resulted in death. Dr. Benjamin Lyle presented a specimen of aneurism of the aorta; also, specimens demonstrating two stages of the spontaneous healing of tuberculous deposits in the lung. Dr. E. W. Mitchell reported a case of sudden

death from angina pectoris. The patient had been a man of unusual health and vigor and never had suffered from symptoms referable to the heart previous to the attack of angina which came on two hours before his death.

The opening of the new Presbyterian Hospital on November 1st was a notable event in the professional and social circles of Cincinnati. The hospital is small, but in point of completeness and the utilization of every advance that hospital science has made in construction and furnishing is not excelled by any. The new structure was erected by Mr. and Mrs. Alexander McDonald as a noble gift to charity. It is located on Kenyon Avenue, directly in the rear of the Laura Memorial College for Women, and may be regarded as supplemental to the old hospital. It is a four-story and basement building of brick and stone. There is an elevator that is accessible from the sidewalk, and when a patient is brought in an ambulance he can be taken to it on the cot and thence to any floor. On the first floor are the chapel, clinical, and drug-rooms. Two free wards, male and female, occupy the entire second floor, and on the third and fourth are twenty-five private rooms. On the third floor are also the operating-room and X-ray compartment, with the latest machines. A special feature of the building is its plumbing, all of which is outside of the walls. Each of the private wards has been furnished by different people. The sun-room for convalescents is on the fourth floor. The building is fire-proof throughout.

The forty-second semi-annual session of the Miami Valley Medical Society was held at Loveland on November 1st, with a full attendance. The meeting was called to order at 10 o'clock in the Presbyterian church by the President, Dr. H. A. Beeson of Leesburg. Dr. J. C. Oliver of Cincinnati read a paper on "Cerebral Compression and Concussion." The paper was full of practical points on diagnosis and treatment. Dr. E. S. Stevens of Lebanon read a paper on "Collapse and Shock from Hemorrhage," Dr. Philip Zenner, by special request, one on the "Causes of Insanity," and Dr. F. W. Langdon one on "Treatment of the Insane."

Dr. R. Morris of Goshen and Dr. Tufts of Hartwell were appointed censors for the coming year. The Committee on Malpractice Suits reported in favor of asking for legislation requiring persons bringing malpractice suits to give security for the costs. The next meeting will be held at Loveland on the second Tuesday of May, 1899.

Mr. Asa Van Wormer has given a renewed stimulus to higher education in Cincinnati by a gift of $60,000 to the Cincinnati University for the erection of a library building. The gift of a like sum by Mr. Briggs Cunningham a few weeks ago has enabled the university to add a much-needed left wing to the main building, a library alone being necessary to complete the buildings.

Dr. C. R. Holmes will remove his free clinic from his private hospital to the O. P. D. of the new Presbyterian Hospital.

The Garrison for Havana Province.—The commission appointed to locate camps for the garrison at Havana have recommended a location eight miles south of the city.

TRANSACTIONS OF FOREIGN SOCIETIES.

London.

THE STUDY OF DYSPEPSIA—PUERPERAL SEPTICEMIA TREATED BY ANTISTREPTOCOCCIC SERUM—THE ASSOCIATION BETWEEN MEDICINE AND SURGERY—MYOSITIS OSSIFICANS PROGRESSIVA—ERYTHEMA FROM AN ENEMA—SOME MOOT POINTS IN THE AFTER-TREATMENT OF CASES OF ABDOMINAL SECTION.

AT the annual meeting of the Medical Society, October 10th, ALLCHIN read a paper on the "Study of Dyspepsia." The immediate causes of indigestion may be grouped as follows: (1) Errors in quantity or character of the food. (2) Diseases of the digestive organs, either (*a*) structural, (*b*) due to impaired nervous control or (*c*) abnormal blood or lymph-supply. (3) Improper bacterial action. (4) Defective absorption. (5) Abnormal intestinal excretory processes.

One of the chief difficulties in studying the subject is the fact that many totally different conditions give rise to similar symptoms. The use of the term "functional dyspepsia" is misleading, as there is always some structural defect. The speaker then took up one type of indigestion, the so-called nervous dyspepsia. The impaired innervation may be of the mouth, stomach, intestines, or associated glands, and the disorder of the nervous control may be of central origin, such as anxiety, hysteria, etc., cerebral tumor, meningitis, etc., or it may be of reflex origin, as from the kidneys, ovaries, etc., or, third, it may be that the nerves of the alimentary canal are irritated. The term nervous dyspepsia, therefore, does not denote a group of symptoms, but indigestion of nervous origin. Hence, there are no absolutely characteristic symptoms, and even by grouping symptoms the ascertainment of the cause of any case of indigestion is extremely difficult.

MAGUIRE laid stress upon the fact that an infant first digests only albumen, as the lactose and finely divided emulsified fat of milk are readily absorbed. At about six months of age carbohydrates are digested, while the power of digesting masses of fat is not developed until much later. In indigestion the powers last acquired are the first to disappear. The ability to digest fat disappears first, then the digestion of carbohydrates is disordered, while the ability to digest proteids continues unimpaired. The rational treatment of such cases is to put the patient for a time upon an exclusively albuminous diet. After improvement becomes manifest carbohydrates may be resumed with caution, diastase being given to aid their digestion. Acids, such as lemon-juice, may be given with fat to facilitate its digestion.

At the Obstetrical Society, October 5th, WALTERS communicated a paper on a case of "Puerperal Septicemia Treated by Antistreptococcic Serum." The uterus had been curetted and swabbed with antiseptic solutions, and for five days there was only slight fever. Then acute and violent symptoms of infection set in, and in addition to local treatment 10 c.c. of antistreptococcic serum were injected. The recovery which followed was con-

sidered to be due in no small part to the injection of the serum.

ROUTH said that it is difficult to say in any given case that the recovery is due to the injections. Out of five or six cases so treated by himself one patient had recovered as a result of the serum alone. He thought it very important to ascertain exactly the nature of the infection before injecting such a powerful agent.

ROBINSON said it would be practically impossible to determine so exactly the nature of the infection. He had examined several cases with only indefinite results. Out of 7 cases which he had treated with the serum, 5 of the patients had died, the treatment apparently having had no effect; 2 of the patients recovered; in 1 of these the only effect was that the patient seemed to sleep better afterward; in the other patient, who had on the eleventh day a temperature of 104° F. and a pulse of 120 and membranous vaginitis, the injections of the serum were followed at once by a fall of temperature and the patient rapidly convalesced.

CULLINGWORTH thought that as streptococci are usually present the serum ought to be given without waiting for bacteriological investigation. The safe rule of practice is to explore the uterus digitally with the finger under an anesthetic (decomposing débris should be removed by the finger, and reliance must not be placed upon the douche), and then administer the serum without delay. Phillips had administered antistreptococcic serum in several cases, but only in one was he certain that the patient's recovery could be attributed to its use. The patient had been for many weeks suffering from acute septicemia. Curettage had failed to produce benefit. Twenty injections were given in the course of twelve weeks. The temperature, which was very high, was always lowered, the delirium ceased and the skin acted, the effect lasting several hours. In this case repeated examinations of the discharges for streptococci gave a negative result. Tate had seen several cases treated by the serum, and in some of them the results appeared to be good. In one case the first injections were followed by improvement, but afterward failed to give relief. Possibly this case was one of mixed infection.

At the first meeting of the year of the Clinical Society, the president, MR. LANGTON, spoke of the "Association between Medicine and Surgery." At the St. Bartholomew Hospital in 1662 the governors had decreed that "the apothecary do not dispense any medicines except such as be ordered by the physicians." Later a relaxation was made, and the surgeons were allowed to order mercurials and purgatives. The topics which are discussed in both surgical and medical societies at the present time show in how many points medicine and surgery overlap. As an illustration he mentioned the treatment of gastric ulcer.

HERRINGHAM narrated a case of "Myositis Ossificans Progressiva." The patient, a girl now aged eight years, was attacked by rigidity of the shoulders when only two years old. This was the result of ossifications in the pectorals and latissimus dorsi. Subsequently the neck became stiff from ossification of the sternomastoids. At five years of age swelling appeared in the back muscles which were attached to the ribs, probably of a fibrous character. At eight years of age the whole back was as rigid as a board. There were bony nodules behind the mastoids, and in the arms, fingers, and toes. There was a pencil of bone nine inches long in the right rectus abdominis. Skiagrams of the right shoulder showed that the joint was normal, the ossification being in the muscles alone. All the lesions of this disease are confined to the somatopleural layer of the mesoblast, and to the bones, periosteum, and connective tissue only. The pathology is uncertain. The trouble is congenital and not hereditary. Males suffer more often than females. There is no adequate evidence of any connection with rheumatism or rheumatoid arthritis. The view of Pincus that it is a form of new growth appears the most reasonable, and parallels may be drawn between this disease and multiple fibromata. The name is unfortunate, but may be retained until its pathology is more certain.

SPENCER regarded the disease as a congenital irregularity of ossification. In certain birds this condition occurs normally, the ossification extending into the tendons from the periosteum.

STILL read a paper on "Erythema Enematogenes (Enema Rash) in Children." This variety of rash is of considerable importance in children inasmuch as it may be easily mistaken for some of the specific fevers of childhood. The rash has a specific appearance and course as is evident from the study of the twenty-six cases which have occurred in the Great Ormond Street Hospital for children. There seems to be no reason to doubt the causal relation of the enema to the rash, as in some children the repetition of the enema repeatedly brought the rash. Their appearance is as follows: Within twelve or twenty-four hours after the administration of the enema a bright red patchy erythema comes out on the front of the knees, the backs of the elbows, the buttocks, and the face. In some cases the rash is scarlatiniform. There is rarely any constitutional disturbance and in one or two days the rash disappears. The amount of the enema or the time of its retention did not seem to have any influence in the character of the rash or the time of its appearance and disappearance. The length of time which constipation had existed did not seem to be of importance. It occurred most often after a first enema. It was more common in children over six years of age, but it had been known to occur in a child only two years old. The absence of pyrexia, of constitutional disturbances, of sore throat and coryza, and the peculiarities of the rash itself will serve to distinguish it from the rash in scarlet fever, measles, and rötheln, with which it is most likely to be confounded. In some instances the rash is followed by desquamation, which adds to the difficulty of differentiating it from scarlet fever. There is some reason to believe that the "surgical scarlet fever" which occurs after an operation is often due to the enema which has been given before the anesthetic. There are three possible explanations of the occurrence of the rash: (1) The absorption of some toxic substance from the soap of the enema; (2) the absorption of fecal toxins which were dis-

solved by the enema; (3) a reflex effect on the vasomotor centers. The author inclined to the second of these possible causes as the most likely, though further investigation is needed to settle the question satisfactorily.

At the British Gynecological Society October 13th MARTIN read a paper on "Some Moot Points in the After-treatment of Cases of Abdominal Section." Complications should be avoided by care in the preparation of the patient and in the perfect hemostasis and asepsis of the operation. Interrupted sutures of silkworm gut passed through the whole thickness of the abdominal wall are to his mind the best form of suture. Wet dressings favor suppuration and powders form crusts. The dressings should be dry and light and the patient should not be confined rigidly to her back for forty-eight hours. The sutures should be removed about the twelfth day. He drains only in septic cases or where there is much oozing. A little clean blood does no harm. He advocated iodoform gauze as a drain in preference to glass or rubber tubes. It is better to drain through the posterior fornix than through the abdominal wall. A hypodermic injection of morphin is advisable immediately after the operation, as also in cases of great prostration and restlessness. He strongly recommended the purgative treatment of peritonitis, preferably by calomel and salines, and discussed the mechanism of their beneficial action. He advised the early administration of bland fluids after the operation; it is cruel and harmful to withhold fluids for forty-eight hours. In vaginal sections he said the vagina should be packed with iodoform gauze and this should be left in until the seventh day. It is unwise to douche for at least a week after the gauze has been removed for fear of forcing the vaginal discharges into the peritoneum. Lastly an abdominal belt should be worn for at least two years after every abdominal section.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK.

Stated Meeting, Held October 22, 1898.

THE President, DR. PALMER C. COLE, in the Chair.

The paper of the evening, entitled

OBSERVATIONS ON THE PROSTATE,

was read by DR. ROBERT H. GREENE. In 214 unselected cases of gonorrhea, taken one after the other as they came to the dispensary, Dr. Greene has carefully looked for evidence of lesions in the posterior urethra and prostate, and has made a careful examination of prostatic secretion after massaging the prostate through the rectum. Forty-five of the cases were first attacks, in 75 it was the second or some "numerically ulterior" attack. In the other cases this detail was not inquired into. In 142 cases, *i. e.*, in more than seventy per cent., careful washing out of the anterior urethra and examination of the urine passed afterward showed that the posterior urethra was involved, bladder trouble having been carefully excluded before making the test. In forty-seven per cent. of the cases there were some signs of prostatic involvement, and an enlargement of the prostate could be made out through the rectum. In 73 out of 92 cases of palpable prostatic enlargement the left lobe was most markedly involved; in 19 cases the right lobe. In the prostatic secretion secured after massage of the prostate there were found microscopically, pus-cells, lymphocytes, leucocytes, erythrocytes, epithelial cells with eccentric nuclei, mucus, and corpora amylacea. The presence of lymphocytes points to the existence in certain of the cases of interstitial change. The subject has not been studied in sufficient detail, however, to enable one to determine in what proportion of cases this occurs.

The writer's conclusion is that the Creator did not make one law for man and another for woman as regards the persistence of changes produced in the genital apparatus by the invasion of the gonococcus. In the one sex, in a large proportion of the cases, permanent changes are induced, or at least lesions which run an extremely chronic course. In the other sex, it has been the custom to think that these enduring pathological processes do not occur, but the more study is devoted to the subject the more is it becoming clear that in man, too, the lesions produced are of the most persistent and chronic character.

In the discussion which followed, DR. RAMON GUITERAS said it was a matter of great interest to him to find in how large a proportion of uncomplicated gonorrheal cases prostatic involvement occurs. He considered that the normal sizes and shapes of prostatic glands in men differ as much as their noses. He has been surprised to find in how many cases careful rectal palpation gave anomalous shapes and sizes of the prostate. He was at first inclined to attribute this to congenital anomaly, but has concluded from some recent cases that the condition is often acquired. He has had occasion to observe the course of several prostatic abscesses which were followed by atrophy of the lobe of the prostate in which the abscess had been situated. In judging of prostatic involvement in gonorrheal cases where it was not a first attack, the possibilty of these changes having been induced by the preceding urethritis or its sequelæ must be borne in mind. He had seen atrophy of prostatic tissue follow purulent processes that seemed to be localized in the epididymis or seminal vesicles.

In answer to a question from Dr. Whitman as to the most satisfactory treatment of gonorrhea at present in use, Dr. Greene said that certainly any method which assumes that the brunt of the attack in gonorrhea is borne by the anterior urethra is bound to be eminently unsatisfactory. As to the methed by irrigation in certain quarters so popular, it is sometimes effectual in stopping the discharge and in seemingly freeing it from the gonococci at an early stage, but relapes are frequent and complications not rare. In the cases in which the infection is limited to the anterior urethra, and there is a certain number of such cases, it is definitely curative. But the older methods must be employed generally until our knowledge of the pathological process in gonorrhea and its mode of spreading are better known.

With regard to a special practical feature of prostatic involvement in these cases and its persistence, Dr. Greene

related a recent experiment with two patients referred to him because they had failed to pass examinations for life insurance. They were to all appearances perfectly healthy individuals, who to their surprise had been refused policies because of some pathological condition of their urine. The insurance agent found out that a few pus-cells had been discovered by the medical examiner in their urine and he absolutely refused to pass them. As they had been applicants to different companies and had been before different medical examiners, it is evident that a good deal of care is being exercised in the examination of urinary sediments. It is not at all improbable that a number of such cases will turn up, as there are others who still have some chronic inflammatory patches in their posterior genital apparatus, the result of early indiscretions, that may occasionally give off pus-cells. Since it would seem that medical insurance examiners have now learned to recognize a pus-cell when they see it more refusals than heretofore may be looked for.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held Wednesday, October 19, 1898.

THE President, L. DUNCAN BULKLEY, M.D., in the Chair.

FIBROID TUMOR OF THE UTERUS; OVARIAN CYST.

DR. ROBERT A. MURRAY: These specimens are presented because in each case the history is unique. The fibroid was removed from a dwarf, four feet six inches high, aged thirty years. At the age of two years she began to menstruate and presented all the signs of maturity. Menstruation was normal and regular until six years ago when she began to flood. The flow was very profuse and lasted eight or ten days. She soon began to show the effect of loss of blood, became excessively nervous, and complained of pain in the abdomen. The tumor was not very large when first discovered. Operation was refused and the patient continued her work in one of the large dry-goods stores. Three years later it was found that another tumor had developed between the vagina and rectum and this caused such severe pressure symptoms that she could with difficulty attend to her duties. Still she refused operation. The flooding continued and her nervousness became intense, the latter being more marked as the menstrual period approached. During the last six months she became so weak from loss of blood that she fainted on several occasions and the condition of her nervous system was such that she had hallucinations and could not sleep without the aid of powerful hypnotics. Meanwhile large doses of ergot, hydrastis, and thyroid extract had been given without any appreciable effect upon the tumor, although the flowing was somewhat controlled by the fluid extract of hydrastis. Electricity, one pole on the abdomen and the other in the vagina, was also employed, with negative results. When the patient finally consented to let me operate I found this large tumor firmly adherent to the left side, and it was removed with great difficulty. Owing to its peculiar position and because of the fact that the pelvis was very much contracted, it was almost impossible to get at the arteries in order to tie them off, but I finally succeeded in doing this from below. Chromicised catgut was used for all ligatures. The abdomen was flushed out with hot saline solution and a quantity of the latter was also injected into the rectum. The abdomen was then closed in three layers, the peritoneum with fine chromicised catgut, the fascia with a running suture of catgut, and the fatty tissue and skin with silkworm-gut sutures. A dressing of sterile gauze was applied. No antiseptics were used during the operation. The wound in the vaginal vault was left open. The patient made a good recovery.

The second specimen is a very large cyst of the right ovary which I removed from a poor scrub-woman who found it very difficult to get employment on account of the large size of her abdomen. She was thirty-nine years of age, the mother of two children, and had ceased to menstruate four years previously. The cyst had rapidly increased in size during the past year. Upon opening the abdomen I found that the cyst was adherent to the under surface of the liver. After eight and a half quarts of chocolate-colored, ill-smelling fluid was evacuated the cyst was freed from its attachment to the liver and intestines and removed. The pedicle consisted of the ovarian ligament, all that remained of the Fallopian tube, and a portion of the broad ligament. The woman, who was extremely emaciated, made an uninterrupted recovery. The sutures were removed on the eighth day and the patient left the hospital at the end of the second week.

In connection with this last case I would like to mention a third in which there is some question as to the exact diagnosis. The patient is a woman, thirty-five years of age, married three years but never pregnant. She menstruated last on September 2d. Just at the time when the October period was expected she got caught in a shower and became thoroughly soaked. This was followed by all the signs of approaching menstruation but the flow did not appear. The patient considered herself pregnant. Upon examination a tumor was found in the pelvis which extends up to the umbilicus and down on the right to the spine of the ilium where it is firmly fixed. The mass also extends to the left side, although not so low down as on the right side. It is solid and absolutely immovable. The ovaries and tubes can not be felt. The cervix is large. There are no signs of pregnancy. The woman complains of but two symptoms, *viz*,, suppression of the menses and difficult defecation. The latter is probably due to pressure of the tumor on the rectum. The patient tells me that she had an attack of peritonitis at the age of seventeen. The family history is bad, her mother and sister having died of cancer of the uterus. The history of the case does not point to fibroid tumor.

DISCUSSION.

DR. J. RIDDLE GOFFE: The speaker should be congratulated upon the success in spite of the many difficulties attending the removal of the fibroid in the first case. The kind of ligature material to be used in these opera-

tions is an interesting point. I am very glad to hear that Dr. Murray is using catgut. I have been using it myself for some years—not chromicised but ordinary catgut, as put up in alcohol by Van Horn & Co.—for all work in the pelvis and also in removal of the uterus per vaginam. The advantage of catgut is that it is absorbed without occasioning any irritation, does not become encysted as silk does, nor burrow around and make a fistula.

The question of the best method of sewing up the abdominal wound is also interesting. For the last few years I have been using through-and-through silver wire sutures, as practised by Marion Sims years ago at the Woman's Hospital, and I find that I get better results and fewer herniæ than when I used to close the abdominal wound in layers. Moreover it is more quickly done.

ASCENDING OPTIC NEURITIS OF PROBABLE SYPHILITIC ORIGIN.

DR. ROBERT H. GREENE: At the May meeting of this society I narrated the history of a case of optic atrophy which had been seen by a number of prominent ophthalmologists, all of whom gave an unfavorable prognosis. In order to encourage the man, who was in a desperate frame of mind on account of his increasing blindness, rather than because I expected any good results, I took him to a friend of mine to have galvanism applied. This has been done by means of one electrode placed on the occiput and the other on the eyes, at daily sittings, and the man's vision is apparently improving, I suppose as a result of stimulation. Of course, if the neuron—the terminal nerve-cell—is dead, nothing can be done to restore sight. I would like to know if any members of the society have had any experience of this kind.

FRACTURE OF THE NECK OF THE FEMUR IN YOUNG SUBJECTS AS A RESULT OF SLIGHT VIOLENCE.

DR. H. LING TAYLOR: At the meeting of the Orthopedic Section of the Academy this week I expect to show two cases of fracture of the neck of the femur in young subjects as a result of a slight fall. We are told in the books that this is apt to occur in elderly people but is rare in young persons except as a result of great violence. Dr. Royal Whitman has collected a number of cases occurring in children. My patients are boys, sixteen and eighteen years of age respectively, and in one case the injury was sustained by falling to the ground while crossing the street, in the other while walking on a piazza.

DR. FRANK GRAUER then read the paper of the evening, entitled

CIRRHOSIS OF THE LIVER, WITH SPECIAL REFERENCE TO ITS ETIOLOGY AND TREATMENT.

The disease was described as a condition in which the liver has become the seat of fibrous changes resembling cicatricial tissue. The term cirrhosis was first employed by Laennec because of the yellow color of the organ but is now used to describe disease of other organs in which there is this overgrowth of fibrous tissue. In cirrhosis of the liver the fibrous tissue is distributed throughout the organ in various ways. In the multilocular or most common variety, it forms a coarse network which involves the whole organ, each mesh enclosing a number of the hepatic lobules. In a second variety individual cells are surrounded by a finer network of fibrous tissue; in a third variety the lobules themselves are penetrated by the new tissue, and in still another dense bands of cicatricial tissue traverse the whole or greater part of the liver dividing it into irregular masses and causing by their contraction a deformity of the organ resembling that seen in so-called gummatous or syphilitic cirrhosis. Clinically the disease is divided into two well-marked types, the *atrophic* and *hypertrophic*. In the former variety the liver is small, weighing in some instances only a pound or a pound and a half. It is usually not adherent. It is tough, irregular in contour, and its surface covered with hobnail projections of variable size around which the capsule appears thickened. On section the organ is generally yellowish-red or jaundiced but at times has a sage-green tinge, and is permeated by a network of cicatricial tissue around islands of liver substance. The large branches of the portal vein are wide but their capillaries are compressed to such a degree that they obstruct the flow of blood in the portal vein.

The hypertrophic variety of the disease is much less common than the atrophic and presents many points of marked contrast. The liver increases in size, weighing from five to seven pounds and at times as much as ten. Its surface is smooth and shows no contraction. On section the organ is yellow or orange-green and its substance smooth or finely granular. It is tough in consistence but not so much so as in the first variety.

The most common cause of cirrhosis of the liver is excessive use of alcohol, compared to which all other causes are insignificant. Of all the organs of the body the liver is the one most affected by alcohol. The next most common cause of the disease is syphilis, either hereditary or acquired. In the former case there is a general fibroid condition of the liver; in the latter a localized fibroid change or scarring of the organ. Malaria has also been given as a cause of cirrhosis of the liver, and in a certain province in Italy it is said to bear a more important etiological relation to the disease than alcohol. The author cited a case of a young woman who developed cirrhosis of the liver after having suffered from malaria for about a year. She was tapped four times to relieve the ascites and died eight months after the onset of the disease. Autopsy showed a large cirrhotic liver and a large spleen, both of which showed the malarial pigment. The gouty diathesis and predisposition to cirrhosis in general are also etiological factors. Tuberculosis is a cause of atrophic cirrhosis. Infectious diseases, such as scarlet fever and even typhoid, play a part in the causation of cirrhosis, and recent work appears to be leading to the conclusion that the disease is brought about by a condition of toxemia.

In regard to treatment, alcohol must be strictly prohibited in all cases of cirrhosis of the liver, whatever the cause. Highly seasoned food, spices, and coffee should also be forbidden. Milk should form the main article of diet at the commencement of the disease. White meat

in small quantity may be allowed later, also vegetables and fruits which contain little starch. If there is any reason to suspect syphilis as an etiological factor, iodid of potassium and mercury should be given. Acids, bitter tonics, and mild preparations of iron may be given to relieve the gastro-intestinal symptoms. Medicine rarely has a permanent effect upon the ascites. In some instances the administration of diuretics is followed by a perceptible diminution of the ascites, and hydragogue cathartics decidedly lessen it. Tapping should be performed early.

DISCUSSION.

DR. R. H. GREENE: The ground has been most thoroughly covered by the paper. One indirect cause of cirrhosis of the liver has not been mentioned, however, namely, heredity. We all know that persons whose ancestors have died of cirrhosis of the liver or kidneys are liable to develop the disease. Such individuals are not considered good risks by the life-insurance companies.

In regard to treatment I believe that in future it will be found that electricity can be used with benefit in cirrhotic conditions of the various organs of the body.

DR. R. A. MURRAY: My experience teaches me that cirrhosis of the liver is generally accompanied by a similar condition of the kidney. I have seen a number of such cases. In acute cirrhosis with ascites I have known markedly good results to follow a single tapping. Two such cases were in Bellevue when I was there, years ago, and both patients are still alive. One of the patients was a saloonkeeper, a whisky-drinker, who was intoxicated when admitted. The other was a stone-mason who had been in the habit of drinking large quantities of beer. Ascites was extensive in each case, and both patients recovered after being tapped once.

I have removed enormous quantities of fluid by tapping these patients, and in one case I tapped nine times during a period of four years. After each tapping the swelling of the abdomen and limbs subsided and the patient was able to return to her business as a teacher of dancing. At her death autopsy showed not only cirrhosis of the liver but a cancerous nodule which pressed upon a vein. It is surprising how long some of these patients live. I have in mind a case in which thirty years ago a professional friend of mine made a diagnosis of cirrhosis of the liver and said that the patient could not live six months. The man had a gouty diathesis but he never developed ascites, and he lived thirty-five years after having been refused by every life-insurance company in the city. In another case the patient was told he could not live more than a few months. This was thirteen years ago. He was a drinking man and at once stopped drinking and has been comparatively well ever since.

DR. S. H. DESSAU: The remarks of the last speaker remind me of a very interesting case I saw in consultation some years ago. The patient, a woman, had a great deal of ascites and had been under the care of several different physicians, and had at one time been in the Rotunda Hospital in Dublin where she was operated upon under the mistaken diagnosis of ovarian dropsy. The interesting feature of the case is that the ascites finally disappeared entirely without treatment, although at the time of her death she showed all the symptoms of cirrhosis.

The author has spoken of phosphorus as a cause of cirrhosis of the liver in children. I have seen several cases of cirrhosis in rickety children who had never been given phosphorus, and I think we may well believe that the rachitis was the cause of the cirrhosis. In one of these the liver decreased markedly in size under the administration of cod-liver oil with hypophosphites. Another cause of ascites in children has not been mentioned by the author, although during the past four years it has been referred to by the French writers, *viz.*, a cardiac lesion at the mitral orifice.

DR. ROBERT MILBANK: I have taken a few notes from my case-book about a case of acute yellow atrophy of the liver in which the symptoms were very similar to those caused by cirrhosis of the liver, and in which a diagnosis of the latter disease had been made by an experienced physician. The following is the history: F. L., aged twenty-two years, mother of two children, came under observation October 10th. She had been fairly well until the beginning of the illness, four weeks previously, which began with nausea, vomiting, headache, and an increasing yellowness of the skin. The vomiting was persistent and occurred at short intervals. She had been in the habit of drinking a good deal of beer, especially at night. When seen by me she had had occasional rigors at irregular intervals, followed by fever and sweating. During the last four days she had complained of a sharp pain in the right side, radiating from the lower border of the ribs toward the right nipple. The vomiting increased and became dark in color. Nutritive enemata and quinin by rectum were given. The patient became stupid and drowsy and later slightly delirious. Death occurred five days after my first visit and was preceded by slight convulsions and coma. Autopsy six and a half hours after death: Lungs slightly congested and edematous; surface of the heart showed areas of congestion; liver weighed two pounds and two drams, and had a yellow, granular appearance, showing considerable contraction on the surface; on section it presented a yellow and red granular appearance; hepatic vessels and ducts were all pervious. Spleen looked very large, but weighed only seven and one-half ounces. Right ovary contained an apoplectic clot. Urinary bladder was full, and examination of the urine showed epithelial casts, leucine, and tyrosin.

DR. H. L. TAYLOR: I was glad to hear the author speak of the effect upon the liver of chronic indigestion. There can be no doubt I think that the toxic products which are the result of chronic indigestion are the cause of many diseases.

DR. WILLIAM STEVENS: It is a mistake to think that patients suffering from cirrhosis must necessarily be hard drinkers. Some years ago I treated a clergyman who was a strict prohibitionist, and in another case the patient drank nothing stronger than unfermented grape-juice.

DR. J. H. FRUITNIGHT: I am of the opinion that

cirrhosis is due to some toxic element, either chemical or microbic. Autopsies made last spring during an epidemic of measles showed the liver to be affected in nearly all cases. I have seen a number of cases of cirrhosis in children due to heredity. As regards the absolute cure of the disease, I doubt if this be possible, although a relatively good state of health may be regained. One should be circumspect in regard to tapping. I once drew off fluid from the abdomen of a patient suffering from an enfeebled condition of the heart. Although I was careful not to remove all the fluid, the patient three hours after the tapping suddenly went into syncope and died.

DR. ROBERT NEWMAN: In regard to the use of electricity in cirrhosis of the liver, I know of instances in which the faradic current has been employed. It seems to me that static electricity would give good results by stimulating the liver and bring it to a normal state.

DR. GRAUER, in closing: In regard to the statement made by one of the speakers as to the connection between cirrhosis of the liver and kidney, the scope of my paper does not include the complications of the disease. It is, of course, well known that those who die of cirrhosis of the liver usually have cirrhosis of the kidney, and from the same cause, *i. e.*, alcoholism.

A complete cure of the disease is not possible, for when fibrous tissue has once formed it cannot be got rid of. What we hope and expect to do by means of treatment is to get rid of the ascites and establish a collateral circulation, such as is described by Osler in his "Practice of Medicine," and in this way prolong the life of the patient for years.

REVIEWS.

A MANUAL OF MODERN SURGERY, GENERAL AND OPERATIVE. Edited by JOHN CHALMERS DA COSTA, M.D., Clinical professor of Surgery, Jefferson Medical College, Philadelphia; Surgeon to the Philadelphia Hospital, etc. Philadelphia: W. B. Saunders, 1898.

THIS excellent abridged volume on surgery appears in its second edition after an interval of four years. In the first edition the author gave the student the benefit of his extensive reading and experience as shown by the liberal quotation of authorities; in its present form, most of the accepted innovations of the past four years have been incorporated, with literary references in each instance. Such methods are commendable for they not only fit the student for subsequent reading, but they tend to preserve the traditions of surgery.

Every chapter has been benefited in this revision. The chapter on bone disease might, however, have been made more lucid for the student by considering any process in the bone as an osteomyelitis, or periostitis (acute, chronic, traumatic, and infectious), with caries, necrosis, sclerosis, plastic formations, and bone-abscess as sequels; these latter would then not be mistaken for diseases *per se*, but would be recognized as the results which they actually are.

The most noteworthy additions are on the surgery of the gastro-intestinal tract. The revised chapter on gunshot wounds harmonizes well with the experiences of surgeons during our recent hostilities. The last few pages are devoted to X-ray work.

THE METHODIST EPISCOPAL HOSPITAL REPORTS. Vol I. 1887–1897. Edited by LEWIS S. PILCHER, M.D., and GLENTWORTH R. BUTLER, M.D. Published by the Hospital, 1898.

THIS report of the young Brooklyn hospital is altogether admirable. It is a historical, surgical, and medical *résumé* of its first ten years of work. The professional part of the work is divided into three parts, the surgical, the medical, and the pediatric. They show that histories are well kept and accurate records established. Dr. Fowler's "Clinical Studies in Appendicitis," Dr. Pilcher's "Clinical Studies of the Surgical Diseases of the Female Generative Organs," Dr. Webster's "The Anesthetizations," and the article on "Surgical Operating-room Arrangements and Methods" (Dr. Pilcher) are instructive and interesting. Dr. Matheson has studied the typhoid cases, Dr. Shaw the cases of disease of the lungs, bronchi, and pleura, Dr. Belcher the cases of aneurism, and Dr. De Forest the cases of pregnancy. Dr. Bogart contributes a study on empyema in children. The 563 pages of the book convey an excellent notion of the hospital's systematic, scientific work. The report is a model of what that of the smaller hospitals should be.

ATLAS AND EPITOME OF OPERATIVE SURGERY. Edited by DR. OTTO ZUCKERKANDL, Privat-docent in the University of Vienna. Translation edited by J. CHALMERS DA COSTA, M.D., Clinical Professor of Surgery in Jefferson Medical College, Philadelphia; Surgeon to the Philadelphia Hospital, etc. Philadelphia: W. B. Saunders, 1898.

THE subject of operative surgery lends itself preeminently to illustration, and in this hand-atlas is represented by twenty-four excellent colored plates and 217 wood-cuts reproduced from photographs. In the text many more operations are considered than are illustrated, which is quite inconsistent with the purpose of an atlas. Surprising is the omission of a number of illustrations of operations on the gastro-intestinal tract, for external urethrotomy, for empyema, for hydrocele, and for operations on the rectum and uterus.

By frequent annotations the translator has brought the work up to date and rendered it more acceptable to the American student. There is nothing distinctively meritorious in this work to attract attention save the distinguished names of the editors.

OUTLINES OF PRACTICAL SURGERY. Edited by WALTER G. SPENCER, M.B., M.S., F.R.C.S., Surgeon to Westminster Hospital. London: Baillière, Tindall, & Cox, 1898.

THIS work is the analogue of our compends, yet the current style of the descriptions makes it more readable than the usual compend with its cut-and-dried queries and answers. It can not be judged by the same standards as

larger text-books on surgery, but it certainly merits the attention of the busy student for the very terse but practical hints in the treatment of surgical affections.

The subject of etiology suffers much because of the step-motherly consideration that bacteriology and pathology receive. Diagrammatic illustrations are used throughout, some of which are very unintelligible; as, for instance, that illustrating Maunsell's operation for intestinal anastomosis. The author assumes a most alarming attitude toward cocain, even gainsaying its anesthetic properties when injected subcutaneously. As an epitome of surgery this text-book might be of service to the student preparing for examinations.

PRACTICAL DIAGNOSIS. The Use of Symptoms in the Diagnosis of Disease. By HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Third edition, enlarged and revised. Philadelphia and New York: Lea Brothers & Co., 1898.

THIS is a companion volume to the author's "Practical Therapeutics" and is arranged upon similarly ingenious lines. The popularity of the book is evident from the fact that it has reached a third edition in three years. The author has improved the present opportunity to bring the work up to the latest scientific discoveries in the art of making diagnoses. The revision is, perhaps, most marked and noticeable in the chapters dealing with the blood and the diseases of the nervous system.

After a lengthy introduction, the author divides his work into two parts: "The Manifestation of Disease in Organs" and "The Manifestation of Disease by Symptoms," the two parts being corollaries of each other, rendering reference and cross-reference easy, and forming a tolerably complete text-book of diagnostic medicine. The grouping of symptoms and assigning them to the various diseases in which they may appear is particularly well done and must prove exceedingly useful to the puzzled practitioner.

Extended review of this work is scarcely called for. The reviewer can but express his gratification that the book has been so carefully revised and can but reiterate that its unique character and thorough usefulness are certain to maintain its popularity. The handsome illustrations and copious index add to the literary excellence of the book.

ACCIDENT AND INJURY; Their Relations to Diseases of the Nervous System. By PEARCE BAILEY, A.M., M.D. New York: D. Appleton & Co., 1898.

THE author has evidently devoted much industry and labor in getting from numerous sources the material which he so ably presents in this book. The work fairly represents the present position of neurological science in reference to a class of diseases specifically due to traumatism. Dr. Bailey frankly states that we are as yet ignorant of the nature of the traumatic neuroses but still much has been elicited in reference to their causes and symptoms. It is the purpose of this book chiefly to offer the latter in such a way as to further their recognition as distinct clinical entities and to render their diagnosis a little more easy.

The book begins with a consideration of injuries to the nervous system of organic character, as well as the effects of such injuries. Part II. deals with the functional effects of injury and the nervous disorders which frequently follow railway and allied accidents, the so-called "traumatic neuroses." An entire division of the work is given to malingering.

Much may be said in praise of this book, its composition and style deserving special comment in this regard. It is comprehensive and shows the labor of a student.

THERAPEUTIC HINTS.

For Gastralgia.—

℞	Morphinæ hydrochlorat. . .		gr. iii
	Cocain. hydrochlorat. . .		gr. v—viii
	Tinct. belladonnæ. . .		ʒ i—ii
	Aq. amygdalæ amaræ .	q.s.ad.	℥ i.

M. Sig. Ten to fifteen drops every hour.

For Vesicular Eczema of Scrotum.—According to WITTZACK it is not advisable to use a powder, since when mixed with the secretion from the affected surface it cakes and falls off. The application of compresses wet with an astringent solution is recommended, as for instance:

℞	Aluminii acetat. . . .	ʒ v
	Liq. plumbi subacetat. . .	ʒ ss—ʒ iiss
	Aquæ	℥ iii.

M. Sig. External use.

If the epithelium is gone it is best to employ a mixture of 1 to 2 parts of white precipitate ointment with Lassar paste. It will often be found helpful to cauterize by means of a solution (10 to 50 per cent.) of caustic potash applied on a cotton tampon; the caustic is then washed off and the part covered by Lassar paste. Or nitrate of silver (a 10- or 20-per-cent. solution) may be chosen.

For Pleurisy with Effusion.—For reasons not yet understood much benefit is derived in this affection, when of tubercular origin, from treatment by mercury added to or alternating with creosote. This is said to be true also of tuberculosis of the lungs, glands, and skin. Occasionally, gastric pain or slight diarrhea is produced, but is easily cured by suspension of treatment for a few days:

℞	Hydrargyri chloridi corrosivi Sodii chloridi Ext. opii	}	aa gr. xv
	Fresh bread crumbs . .		gr. lxxv
	Gluten		gr. xl
	Glycerini		*m.* xxx—xlviii.

M. Ft. pil. No. C. Sig. One to three pills daily during a meal.—*Robin.*

For Flatulence in Children.—

℞	Sodii sulphocarb. . . .		gr. iv—viii
	Syr. aurantii		*m.* xl
	Aq. menthæ pip. .	q.s.ad.	℥ i.

M. Sig. One teaspoonful three times a day for two days.—*Freyberger.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIII. NEW YORK, SATURDAY, NOVEMBER 19, 1898. NO. 21.

ORIGINAL ARTICLES.

THE TREATMENT OF PNEUMONIA IN CHILDREN IN HOSPITAL AND GENERAL PRACTICE.

DISCUSSION HELD IN THE SECTION ON PEDIATRICS OF THE NEW YORK ACADEMY OF MEDICINE NOVEMBER 10, 1898.

THE MANAGEMENT OF THE FEVER OF PNEUMONIA.

BY HENRY DWIGHT CHAPIN, M.D.,
OF NEW YORK.

IN the discussion of the management of the fever of pneumonia no distinction will be made between the catarrhal and croupous forms of the disease.

It has seemed to the writer that undue prominence is often given to this symptom and energetic measures sometimes needlessly taken to combat it. Of course, high temperature in connection with inflammatory action in the lungs is naturally to be expected. It is quite possible that a certain grade of fever may have a beneficial action when it accompanies the reaction of the tissues to infective and inflammatory irritation. It is also a clinical fact that children, as a rule, stand high temperature well. When this is the case it is folly to upset the stomach by drugs or weaken the heart by antipyretics in combatting a temperature that is not doing any great harm. In such a case the treatment may do more damage than the symptom against which it is directed. As the inflammation of the lungs subsides, the fever will subside, and in many cases the careful treatment of the disease by well-known methods will, at the same time, constitute the best management of the fever. There are times, however, when a single symptom will reach preponderating importance and call for special treatment. This may be the case with the fever of pneumonia. Children vary much in the way they are affected by fever. Some bear very high temperatures without evidence of much disturbance. In others hyperpyrexia will have a disastrous effect upon the brain and nervous system, upon heart and lungs, and upon the digestive organs. Here interference is promptly called for and the indication for treatment is not so much the exact degree of temperature as the disturbance which is being caused by the fever. In one case a temperature of 102° to 103° F., may call for special treatment; in another there may be good toleration up to the point of 104° or even 105° F. A glance at such disturbances may aid in indicating the call for treatment. High temperature may result in extreme cerebral irritation, producing great restlessness, insomnia, and convulsions. In other cases, especially infants, there may be stupor, and even coma. The heart sometimes becomes weak as well as rapid in action. When the temperature is very high, accompanying this condition we have a marked increase in the rapidity of respiration. This may be of serious import in pneumonia where the respiratory action is more or less embarrassed. For example, a rise of two degrees, from 103° to 105° F., may quicken the respirations from 40 up to 50, 60, or more per minute. This adds to the exhaustion and increases the spread of the congestion and inflammation. The heart also experiences more difficulty in sending the blood through the engorged lungs. Digestion and assimilation always suffer more or less in fever. In some cases this disturbance may be so serious as to impair the chances of recovery.

While a high temperature may not be the exclusive cause of the conditions just enumerated, as various degrees of toxemia and nephritis may co-exist, it has been shown by experience that control of hyperpyrexia gives a certain measure of relief. It must be remembered that the temperature of pneumonia in children is rarely continuously high, there being frequent remissions in the average normal course of the disease. In croupous pneumonia the indications for interference in hyperpyrexia are not so important as in bronchopneumonia, as the former disease runs a short course and tends to recovery in children, even with severe nervous symptoms and very high fever.

In our management of hyperpyrexia, the first point is to avoid any measures that will secondarily have a bad effect, and thus hinder future chances of recovery. All depressing remedies come under this head: as, for example, most of the coal-tar derivatives. The only exception I make to this rule is the occasional administration of small doses of phenacetin in sthenic cases where there is pain and nervous restlessness. Cardiac stimulants, such as caffein or camphor, are always added. Where very high temperature keeps recurring, however, this remedy

is not to be continued. Antipyrin, and especially acetanilid, should not be given under any circumstances. It is sometimes a great temptation to give these preparations as they are easily taken and usually have a prompt if only temporary effect. The application of water is on the whole the safest and most satisfactory method of controlling dangerous hyperpyrexia. Much may be accomplished by a thorough application of cold to the head. This not only reduces the temperature but relieves to a certain extent its deleterious effect upon the brain and nervous system. In order to be effectual the cold to the head must be thoroughly and continuously applied. The ordinary method of applying cool cloths is not sufficient. Finely cracked ice placed in bladders, from which the surplus air is expelled, may be molded around the head, especially at the vertex and occiput. I have found ice-poultices, made by mixing finely cracked ice with flaxseed meal in oiled silk, placed around and on top of the head, to be most valuable. By this means a steady application of cold can be conveniently applied. If this is not accomplished, the next resource is the application of compresses directly to the chest. The child is stripped, wrapped in a blanket, and placed upon a table. A stimulant is given and the feet are placed in contact with hot bottles. A compress sufficiently large to surround the chest is plunged into water at a temperature of from 70° to 95° F., and applied to the chest. This is changed every ten or fifteen minutes until the desired result is obtained. In order to disturb the child as little as possible, the nurse is directed to apply the compress from the front, tucking in the ends until they meet in the back, in this way avoiding much movement or inconvenience to the child. The exact temperature of the water in a given case must be determined by the condition of the child, and the temperature to be combatted. A needless amount of cold is often employed. If the temperature is 105° F., the water may be 95° F., or even warmer at the start. A frequent application of the compresses will often produce results at this comparatively high temperature. If the compresses are allowed to remain unchanged, they become warm and the effect is lost.

If the temperature does not yield, the temperature of the water can be lowered until it reaches 70° F., 60° F., or even lower. It requires some careful watching to determine exactly how low the temperature of the water may be kept. The addition of about one-fourth part of alcohol sometimes increases the value of these compresses. This was well exemplified in a case recently under my care. An infant fifteen months of age with an extensive bronchopneumonia had a temperature ranging from 104° to 105° F. As the symptoms were somewhat urgent, the infant twitching as in beginning convulsions, a compress at 60° F. was applied about the chest. The child became slightly cyanotic under the compress, without much reduction of temperature. They were then removed and stimulants given. The following day compresses at 70° F., with the addition of one-fourth part alcohol, were applied, and the child reacted well to this treatment; the temperature soon dropped to 102° F. *So long as the feet and hands are kept warm* the cool compresses may be applied, but chilliness of these parts is a contraindication to cold. When the temperature is reduced to 102° or 103° F., the compresses should not be renewed, but are kept in position in case the temperature ascends again to an unsafe degree. In the meantime they act in the same way as a cotton-batting jacket. I have sometimes kept a child in this position for several days, applying cold when indicated by a hyperpyrexia which tends to recur. This clinical fact is probably explained by a mixed infection and not the pneumococcus alone being responsible for the disease. Wide variations in the temperature point to the former condition.

The deepened respirations ensuing upon the application of the compresses have a favorable effect upon the pneumonic circulation. As a rule, children do not object to the compress when applied in the manner here suggested, the principal point being to avoid too great a degree of cold and to apply the compress with as little disturbance as possible to the child, keeping the extremities warm.

Although I have occasionally employed the tub I rarely use this method now in combatting hyperpyrexia. The fright of the child and the exhaustion which accompanies the tubbing contraindicate its use. I believe that all the good effects which may be obtained by the use of the tub may be had by a proper use of cool compresses. In case of cyanotic children, with prostration and hyperpyrexia, I have employed the warm bath (100° F.) with friction of the surface with good results.

THE TREATMENT OF PNEUMONIA IN VERY YOUNG CHILDREN.

BY L. EMMETT HOLT, M.D.,
OF NEW YORK.

IN considering the treatment of a disease like pneumonia it should be borne in mind at the very outset that most of the cases of primary pneumonia seen in fairly vigorous children more than two years old recover. If of the lobar type they are usually single-lobed and uncomplicated, often severely ill but terminating usually by crisis. If they are cases

of bronchopneumonia they do not usually lead to diffuse areas of consolidation, although in most instances both lungs are affected.

The cases just described form fully two-thirds of those seen in private practice, although they make up a much smaller proportion of those seen in hospitals. The great majority of these patients recover and recover promptly with hygienic treatment only. Very active treatment is unnecessary. In a great proportion of them stimulants are not required and, with the exception of an occasional dose of medicine for some special symptom, they get well without drugs. Cases like these prove nothing for any plan of treatment. It is in the hospital surroundings in delicate children, and particularly in those under two years old, that the crucial test of any plan of treatment for pneumonia in early life is found. Dropping, therefore, for the present, from consideration the milder group of cases, let us consider only those of the serious type among the class of children mentioned.

There are three ways in which pneumonia in young children may kill, or rather, three types of the disease which may be fatal: (1) From exhaustion; (2) from complications; (3) from acute toxemia. Judging from my own hospital service I should say that the relative frequency of these causes of death is about sixty per cent. from the first, twenty-five per cent. from the second, and fifteen per cent. from the third.

In the first class, in which death occurs from exhaustion, it is not generally because the attack is an especially severe one, but because of the diminished resistance of the patient in consequence of its age, and often of its previously debilitated condition. Such a child, one year old let us suppose, has pneumonia. What can we do for him? At the outset we must recognize the fact that there are many things which may be of value when given to older children and to adults which are not admissible in the case of these little patients. As we cannot do all that we would we must content ourselves with doing as well as possible the things which are of greatest importance. We have as yet no specific remedy for pneumonia, no pneumococcus antitoxin; we can do nothing directly to neutralize the poison of this organism or prevent its development. Both these ends are best accomplished by increasing the resistance of the tissues of the patient, in other words, by treating the child rather than the disease. It should be our purpose, therefore, so to care for the child as shall best enable it to resist the advances of the disease. The most important things to be considered are: (1) an abundance of fresh air; (2) intelligent nursing; (3) careful feeding.

An adequate supply of fresh air is always essential to good nutrition and is absolutely indispensable when the lungs are the seat of the disease. Under no circumstances should less than 1000 cubic feet be allowed to each hospital patient, and, more than this, when possible, will improve the results. Rooms kept close and suffocating at a temperature of 75° F. and upward, on account of the fear of draughts, so often encountered in private practice, are to be reckoned among the most depressing agencies to a child with pneumonia that can be imagined. In the Babies' Hospital where several patients are together we endeavor to have them taken from the ward two or three times a day to another room where a complete change of air can be secured and to allow thorough airing and ventilation of the ward they have vacated, the temperature of both wards being kept at about 70° F.

No less important than this is the constant, unremitting, intelligent care which is included under the term of good nursing; not to worry the child and wear it out by doing too much, quieting its nervous system by frequently changing its position in its crib and changing from the crib to the nurse's lap or shoulder, and ministering to its physical comfort in the thousand and one little ways which an experienced infant's nurse knows how to do. One nurse will quite wear a child out with the fretting and crying and continued resistance which her attentions excite. Another will quiet and soothe it and accomplish everything which is necessary with half the struggle, and often with none at all. The effect of these things upon the welfare of the patient is something which is hard to overestimate.

The third essential is careful feeding, observing closely the particular child under treatment, lest we upset completely the digestion already enfeebled by the acute disease. Plenty of water is always important and is best given by combining it with the food, which is thus made more dilute than in health, together with the use of predigested milk and beef preparations, or other foods which are easier assimilated and tax digestion as little as possible. Few things cause a child to lose ground so rapidly as an attack of acute indigestion, usually the result of overfeeding, and when the stomach has once failed it usually happens that all is lost.

In the cases we are now considering death rarely occurs before the end of the first week and more often not until the third or fourth week, the usual local condition being a gradual extension of the inflammatory process until there are quite extensive areas of consolidation in both lungs and a progressive exhaustion of the child. Very often these attacks are not severe at the outset.

In addition to these general means, which must in

all cases be attended to, some special symptoms may require treatment. The cough in our experience has been better controlled by the inhalations of the vapor of such substances as creosote, eucalyptol, and pine-needle oil under a tent than by the administration of drugs by the mouth. Some stimulation is required in nearly all cases, at least after the first few days, and sometimes wine, sometimes brandy or whisky is better borne. Both should be very freely diluted and rarely pushed beyond 1 ounce of whisky or 3 or 4 ounces of light wine in twenty-four hours. Often we have found it better to give the food during the day and stimulants chiefly at night. The temperature is rarely high enough in these cases to require anything more than sponging or an ice-cap to the head. Moderate counter-irritation, especially early in the disease, is usually maintained by the use of a mustard paste every three to six hours, left on from five to six minutes; and an oil-silk jacket is worn throughout the attack. By such means as this, rather than poulticing the chest, and the internal administration of expectorants, antipyrectics, and large amounts of alcoholic and other stimulants, such cases of pneumonia are, in our experience, best managed, whether they occur in hospital or private practice. The rule should be followed of not giving the child a single dose of medicine unless absolutely demanded.

According to our division the second group of cases are those with complications. These are generally the result of the infection of other organs by the pneumococcus, the order of frequency with which they occur being plastic or purulent pleurisy, pericarditis, meningitis, and peritonitis. These are sometimes seen early and sometimes late. For such cases no special treatment is required beyond that for any other severe case. Except pleurisy, these complications, I believe, are invariably fatal in infancy and even pleurisy is very serious. Beyond the local treatment for empyema complicated cases are managed like other serious cases of pneumonia.

In the third group we have placed cases characterized often from the outset by an intense toxemia, the prominent constitutional symptoms being hyperpyrexia, profound prostration, and cerebral symptoms, the local condition being, first, one of intense congestion and edema, and later widespread disease involving usually more than one lobe or both lungs. Exceptionally, however, severe toxic symptoms occur with a local disease of only moderate extent. In this type of pneumonia death may result in the first twenty-four hours, the patient being overwhelmed by the violence of the onset of the disease. It nearly always proves fatal, if at all, before the end of the first week.

The treatment of these cases must have regard both to the constitutional and to the local conditions. Cardiac and respiratory stimulants are often necessary within twelve hours of the onset and invariably before the end of the second day. Those stimulants on which we most rely, placed in the order of their value according to our judgment are: (1) Strychnin, (2) nitroglycerin, (3) oxygen, (4) alcohol, (5) caffein. They may often be given hypodermically with advantage. Of strychnin we rarely for a child of one year give more than $\frac{1}{200}$ of a grain every three hours, except for a very short time and it must sometimes be omitted altogether when there is great restlessness and cerebral excitement. Nitroglycerin we find especially useful in the early stage of the disease with a pale face, feeble pulse, and cool extremities and signs in the chest of an intense pulmonary engorgement. Here, by its effect in dilating the peripheral vessels, it may, in conjunction with hot mustard baths, accomplish more than everything else in getting the blood out of the lungs. For a short time $\frac{1}{400}$ of a grain may be given every hour, and after two or three doses continued at four- or five-hour intervals. Alcohol, though very useful, is, I think, very apt to be pushed too far and it is distinctly inferior to some of the drugs mentioned. It is seldom necessary, except for a few hours at a time, to give more than 20 drops of brandy hourly or an ounce in a day. Oxygen is of the greatest value, but unfortunately its expense makes its routine use almost impossible in hospital practice. Caffein in $\frac{1}{10}$-grain doses will sometimes act better than strychnin, particularly in dull, drowsy patients, so poisoned by the disease that the administration of food and stimulants becomes extremely difficult. The question of feeding in this form of pneumonia is much less important than in those previously referred to. On account of the difficulty of administration and the feeble digestion we find it advantageous in many cases to employ forced feeding by means of the stomach-tube, completely peptonized milk being the food most generally useful.

Hyperpyrexia is best controlled by the cold-pack, all clothing but the napkin being removed. The child is laid upon a blanket, then rolled in a wet sheet, and afterward rubbed with ice over the trunk. The blanket is then brought together and pinned beneath the chin without removing the wet sheet. The ice is reapplied every one-half hour or two hours, according to the symptoms. The wet-pack may be continued for two or three days at a time. A hot-water bag should always be kept at the feet. Used in the manner indicated, I have never seen any bad results follow this means of reducing temperature, and have been thoroughly satisfied with its effect. I

believe it to be the simplest and most efficient means at our command.

Hot-mustard baths have already been alluded to. They should be given at a temperature of 105° to 106° F., this being tested by a thermometer (lest the child may be scalded), and continued from ten to twenty minutes. They may be repeated every five or six hours.

These patients demand the closest watchfulness on the part of both nurses and physicians, but are sometimes among the most satisfactory ones with which to deal. If possible, a physician or a nurse of wide experience should always be at hand, since the issue of the case may turn upon doing the right thing at a critical moment. There are two or three cautions which I believe should be emphasized in the management of these cases. I believe we should be very cautious in using in young children such powerful drugs as those mentioned, and should carefully note the effect upon the pulse, respiration, and nervous system of small doses before giving larger ones. Great, and I think at times fatal, injury is sometimes done by overzealous medication. Another thing is the value of rest. I have known children to have so much done for them that they were simply worn out on account of the constant disturbance for feeding, baths, medicine, stimulants, enemas, etc.

By way of summary I would lay stress upon the following points in the treatment of pneumonia in very young children:

1. No depleting measures are ever admissible.
2. Hygienic treatment including fresh air, proper feeding, and intelligent care is of the utmost importance.
3. No unnecessary medication should be permitted.
4. Many annoying symptoms may be relieved by local treatment, such as the cough by inhalations, pain by counter-irritation, restlessness by the ice-cap or sponging.
5. Stimulants should be deferred until demanded by the condition of the pulse.
6. High temperature is much more safely and effectively controlled by the use of cold than by drugs.
7. Greater caution is necessary in the use of powerful stimulants than is generally observed.
8. Rest is quite as important as in in other serious diseases.

A Tablet in Memory of Doctor Gibbs. — At the 132d Anniversary of Rutger's College, recently celebrated at that institution at New Brunswick, New Jersey, a tablet was unveiled to the memory of Doctor John Blair Gibbs of New York, who fell at Guantanamo, Cuba. The tablet was presented by Professor Robert W. Prentiss, who, with Doctor Gibbs, graduated from Rutger's in the class of 1878.

THE TREATMENT OF PNEUMONIA IN INFANTS AND CHILDREN.[1]

BY HENRY KOPLIK, M.D.,
OF NEW YORK;
ATTENDING PHYSICIAN TO THE GOOD SAMARITAN DISPENSARY; ADJUNCT ATTENDING PHYSICIAN TO THE MT. SINAI HOSPITAL (CHILDREN'S WARD).

THE treatment of uncomplicated pneumonia occuring in infants and young children must and will remain for a time a matter of much discussion and honest difference of opinion. Our knowledge of the etiology of pneumonia has made immense strides, but this new knowledge has not as yet revealed any specific remedy in the treatment of the disease. The new facts in etiology have, however, had a tendency to broaden our methods. Whether we have reduced the mortality is a matter of much question. Acute primary broncho or lobar pneumonia in infants and young children is an infectious disease and the lines of treatment will be largely influenced by this fact. In a case of pneumonia, uncomplicated and primary, the treatment whether the disease be of the bronchopneumonic or the lobar type will be guided by much the same general principles. The treatment can never follow any hard and fast rules as to measures actively employed. There are certain things which aid the patient and others which it is well always to avoid. The treatment must be influenced by the (*a*) age of the patient; (*b*) the severity of the infection and the amount of lung involved, and (*c*) the condition of the heart. On these broad common lines we can all approach the treatment appropriate to the case.

In very young infants and the new-born, the mortality being very high, it is evident that much greater discretion is required in the selection of remedies than at a later period of life. At this tender age the indications are also much more difficult to interpret and to carry out. The temperature at this early age, in some very severe types, is subnormal; you would, therefore, be at once relieved of the necessity of considering any antipyretic measures. Your attention is drawn to another direction. The following case will illustrate this phase of the subject:

Female infant, three months and three days old; breast-fed; weighs 9½ lbs.; is well covered. It has been ill for three days with a cough, dyspnea, and refuses to take the breast. Examination reveals a very mild degree of cyanosis, great dyspnea with a harrassing cough and frothy expectoration. Lung reveals a pneumonia in spots on both sides of the chest, behind and in front, and areas of collapsed lung, especially over the upper lobe behind on left

[1] Read in the Section on Pediatrics of the New York Academy of Medicine, November 10, 1898, in the discussion on "The Treatment of Pneumonia in Children in Hospital and General Practice."

side. Heart, 210 beats to the minute; respiration, 50; temperature 99° F. in the rectum; urine contains a trace of albumin; no casts.

In this case the intensity of the infection and the excessive heart-action would first claim our notice. An infection which involves areas disseminated over both lungs and which drives a heart at the rate of 210 contractions per minute will soon exhaust such a young infant unless we are able to aid the heart and overcome the poison of an infection so profound. The subnormal temperature is also a very strong argument against those who always contend that the bath (cold) treatment is the sheet-anchor against the spread of infection; in other words, the temperature is a measure of the infection present. This is not so. And here let us take up the question of infection as it presents itself. Have we anything that will directly combat an infection so intense? We have not. Some years ago, R. von Jaksch thought that he had discovered such a means. He argued that in pneumonias of children, especially of the lobar type, the leucocytosis which is present in most cases and which increases at the approach of the crisis is absent in some of the cases in which infection is profound. The patients succumbed directly because of the absence of this salutary leucocytosis. He thought he had found in phenacetin a drug which would favor the production of a leucocytosis in cases in which this blood state was absent, and thereby the crisis could be hastened, nay assured. All this has since been cast much in doubt.

In a case such as has been related above we must reduce the pulse and support the heart. In these cases small doses of digitalis, the tincture, or tincture of strophanthus stand us in special need. The latter drug sometimes is much better borne by the patient. If we use digitalis when the pulse-rate is high and there is threatened collapse of the right ventricle, we must give the drug in ½ minim doses frequently repeated until the desired effect is attained. Former practice was to give aconite both in these cases and in those in which the temperature was high. To reduce the action of a heart by weakening it as aconite does is not as safe, at least to the right ventricle, as the mode of reduction effected by digitalis. In these cases we will do best not to administer nitroglycerin in threatened or actual edema of the lung. The experience with this drug at the bedside of very tender infants is discouraging; its action is too rapid and evanescent and it seems to favor the very condition, an eventual cardiac failure, which we desire to avoid. Camphor, ammonia, caffein, and musk, also, are not sustained in action. Strychnin in doses of $\frac{1}{100}$ of a grain given hypodermically is a very useful drug.

In cases of sudden acute heart-failure our main reliance must be placed on hypodermics of alcohol and ether; first the latter, then the former. In cases such as detailed tepid or warm baths always seem to have a stimulating effect tending to restore the circulation and to draw to the skin the blood which has been driven into the interior.

Poultices or cataplasm do not work any good, nor can their use be justified on any scientific grounds, either in the above set of cases or in any form of pneumonia. Opium is very badly borne, and in these young infants with asthenic symptoms, only tends to deepen the stupor into which the disease and its poison seems to have plunged the patients. Opium is distinctly contraindicated in weakly, idiotic, or semi-idiotic infants; they seem to bear the drug very badly. The following case belongs to this type, the patient being treated for an extensive double pneumonia two weeks in duration without opium:

Bronchopneumonia.—Mongolian idiot; weak heart; recovery. Male; weakly infant eight weeks old; had been ill some days, mother says four, before being seen; is breast-fed, and weighs about six pounds; is built quite small, but is not emaciated. Examination shows a pneumonia in right lung, lower lobe, behind, and in the left lung; disseminated areas in both lungs. At base of both lungs there does not seem to be expansion; air is not heard entering.

In this case there was a constant cyanosis, the chest walls did not expand but were sharply drawn in at the lower portion. There was evident lack of action of the intercostals and the infant was in addition to pneumonia suffering from collapse of the lung. Recovery took place slowly within fourteen days, with recurrence of temperatures for fully a week; lung gradually cleared. No baths given, no antipyretics though the temperature was constantly high. The heart alone received treatment in the form of tincture of strophantus in small doses.

On the other hand, allow me to direct your attention to a case in which there was a constant high temperature in which there was a set of severe nervous symptoms. Yet it would be out of question to treat this patient by cold baths or too energetically with warm baths; nor could we resort to antipyretics on account of extreme cardiac weakness.

Pneumonia.—Intense infection; convulsions; tetany. Female infant five weeks old; is quite small, but not atrophic; is well covered; had been ill for two days previous to visit; breathes very rapidly; little or no cough; does not nurse; bowels regular, and we find nothing abnormal in the examination of the feces.

On examination we find a pneumonia on the right

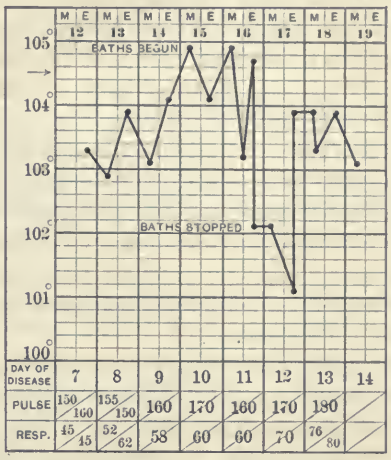
side behind above spine of scapula, also over lower lobe; fine crepitations. Left side behind, dulness and bronchophony over the middle of the chest in small areas; crepitations over rest of lung; pulse very flickering and scarcely to be counted; heart sounds normal; liver normal; spleen normal. There is an appearance of great prostration; peripneumonic groove depressed.

In two days convulsions set in without any marked spread of physical signs. The infant was in a state of constant tetany with opisthotonos; preceding this state of constant rigidity, the infant had convulsions in which it stopped breathing; pulse became scarcely perceptible; it became blue in the face, and its pupils dilated. Under ether injections pulse would return and color become normal and pupils contract. Such attacks would recur at intervals. After twenty-four hours this state gave way to tetany, which involved the extremities and muscles of the neck, at times with exacerbation of opisthotonos. After three days edema of the lungs set in with a heart acting very indistinctly; pulmonic sounds scarcely heard. The treatment in this case endeavored to support the heart and alleviate the condition of tetany by nerve sedatives.

In young infants suffering from a bronchopneumonia of the varieties detailed above, some clinicians of vast experience have urged the use of an emetic, either turpeth mineral or antimony in the course of the disease to rid the bronchi of an accumulated secretion. This is always of questionable utility, for emesis is produced only at the expense of the heart in these cases.

Let us turn to a type of pneumonia in infants in which the symptoms are of a more sthenic variety, though the infection is just as profound as in the first type: Infant five months old, male; bottle-fed; no hereditary history. October 5th was taken ill; had signs at first of a general bronchitis, which soon gave way to signs of pneumonia. Was seen on the tenth day of the disease in consultation. Found an infant well nourished but pale and slightly cyanosed at the lips; great dyspnea; respiration, 60; pulse, 170; temperature from 104° to 105° F.; pneumonia fully developed in the lower lobe of the left lung, giving dulness, bronchial voice and breathing and crepitant râles; four or five bowel movements, varying from yellow to greenish and more fluid than normal. Temperature being high and there being some twitching of the facial muscles, baths were at once resorted to; baby put in bath at 85° and water reduced to 75° F., duration five minutes. The reduction of temperature was slight, 1° at first, and after bath condition was not improved; the baths were repeated every three hours with result shown in chart. Here the infection was so extreme as to involve also the bowels, which toward the exitus gave much concern in the case.

Chart A.



The temperature tracings in case of infant five-months old.

In this case not only the heart but the constantly high temperature claimed active interference. Baths were not well borne toward the close, either cold or warm, after several had been given; the heart was supported by means already detailed. Baths were discontinued for reasons shown in the charts.

Temperature tracings showing remissions after the baths, which were given every three hours, from 9.30 A. M., October 15th, to 4.30 A.M., October 16th.

On the other hand, in infants from six to nine months in whom the pulse is good and the temperature is high and in whom even the amount of lung

involved is considerable, baths are well borne when indicated. A temperature above 104° F. for two days is a plain indication for bathing or cold pack. Frequent baths of any kind are to be deprecated. They tend to an effect contrary to what we strive for. It is said that the baths do not palpably reduce temperature in these cases. This is frequently so, and yet in many cases they seem to refresh the patients if given no more than twice or three times in twenty-four hours. Jurgensen explains the beneficial effect by the fact that though in some cases the real remission of temperature is not great the sum aggregate of the small remissions is considerable.

The following case seen in consultation will well illustrate how a normal bronchopneumonia will act under skilful management.

Female, aged seven months; weight, approximately, eighteen pounds; bottle-fed; sick eight days. Area of bronchopneumonia, lower right lung in axilla and upper part left lung. Temperature, 104.5° F.; pulse, 130; respiration, 60; general condition excellent. Sponge baths of cold water reduce the temperature several degrees without signs of collapse. In addition drop doses of tincture of digitalis are given, and some little opium and ipecac. Here very little medicine was being given, the food was limited to less than the amounts allowed in health. Sponging was indicated not only by the temperature but by some nervous twitchings of the muscles of the hands and face. The cardinal guide is never to repeat a bath, warm or cold, unless it is found that with the reduction of temperature, whether this be slight or marked, the heart-action remains good. There must be no symptoms of exhaustion or collapse. Some infants and children will not bear baths, warm or cold, of even momentary duration. They become blue, threaten to stop breathing, and the pulse at the wrist becomes almost imperceptible. In giving the first bath it is well for the physician to be at hand and ready to counteract the bad effects should they appear. Sometimes, as in cases related by Jurgensen, these effects only appear after many baths. It is then we have a distinct indication to discontinue. Never give baths when the temperature has started on a decline (see chart), temporary or permanent. All men of large experience have had scores of cases in these infants which have been treated successfully without baths. This is especially so when the means of carrying out the treatment are not at hand. In these cases small doses of the antipyretics are of great value. These drugs have been brought much into disrepute through the administration of large doses, too large for the age of the infants. Infants aged six months to a year will bear from ½ to 1 grain of antipyrin or phenacetin combined with digitalis in ½ to 1-minim doses quite well. Opiates in these older infants who have what might be termed a normal type of pneumonia is well borne, but only in small doses, never hypodermatically. Opium here is rather a stimulant and relieves pain to a certain extent. We should use in these infants the weaker preparations of opium such as the camphorated tincture or wine. In infants in whom the pulse is good and respirations are not excessive, digitalis, strophanthus, or strychnin are rarely called for. Without any hereditary weakness or taint these stronger infants, in whom the amount of lung involved limits itself and the infection is not great, do very well on an ultra conservative treatment.

In older infants, from the age of one to two years, in whom the amount of lung involved is not large and remains limited; in whom the heart action and pulse are good even though the temperature remains constantly above 103° F., even mounting to 105° F., the tendency is to get well and therefore the physician finds himself called upon to do very little beyond relieving the cough and pain. In these cases the safer practice is to use the milder preparations of opium by the mouth, some minute doses of ipecac and in most cases a small dose of antipyrin or phenacetin not only to combat the temperature which is questionable, but also partly to relieve the pain and quiet the patient. Yet in these cases at the bedside the eagerness of the physician to apply baths and to do this every few hours is baffling. The temperature alone is not a safe guide. We expect a temperature in pneumonia. Nor is the temperature of the same significance as in typhoid fever. In the latter disease a much lower temperature is an indication for baths than in pneumonia. The temperature is not sustained enough through weeks to work the injury to the heart that it does in typhoid fever. In a normal case of pneumonia the danger of a high temperature involves the nervous system as well as the heart. A temperature above 105° F. for any length of time will soon bring on phenomena on the part of the nervous system, such as twitchings, convulsions, and tetany. Here we should resort to baths.

The more we see of infants who suffer from a normal type of pneumonia, that is, the type in which the heart is well sustained in action and the area of lung involved limited, the less we resort to alcohol. In fact only in the asthenic cases is it of use and then not to the extent that we were accustomed to think in past years. It seems that the good effects of alcohol in pneumonia of these infants have been much overestimated. In many cases the alcohol does harm by driving the heart, reducing the appetite and capacity for digestion. Alcohol in many cases

causes vomiting and nausea. We thus lose our hold on one of the principal factors in the recovery of the case, the sustained nutrition of the patient.

This paper cannot be closed without the consideration of a few facts which are constantly forgotten. The patient should be isolated from other children. Ventilation, the constant change of air, is as necessary in the management of these cases as it is in a state of health. The temperature of the sick room if feasible should be kept at about 65° to 70° F. The impregnation of the atmosphere about the patient with thymol vapor, turpentine, or creosote vapor is of very questionable utility.

TREATMENT OF BRONCHOPNEUMONIA COMPLICATING MEASLES.

BY WALTER LESTER CARR, M.D.,
OF NEW YORK.

THE bronchopneumonia of measles is most frequently observed in children whose vitality is depressed from rachitis, pertussis, tuberculosis, etc. It is also seen when there is no history except that of the rubeola.

A patient with measles should be kept in a well-ventilated room at an even temperature of 65° to 70° F., and the air moistened by the evaporation of water from an open vessel or by steam if there be much laryngitis or bronchitis. The nares are to be washed with a boric-acid or salt solution at a temperature of 100° F. A small, soft rubber bulb syringe is to be used and the cleansing done often enough to keep the mucous membrane clear of secretion. The skin is to be stimulated by water at a temperature of 100°–105° F., to which a small quantity of alcohol is added. With babies and children of low vitality friction between the scapulæ and in the axillæ is serviceable. The diet is to be simple and easy of absorption. Milk is a good food, but it is not always digested when given undiluted; it must then be given pancreatized or prepared as best suits the case.

If, however, the endeavor to prevent the invasion of the lung is not successful, we should redouble our care and attention. The patient is to be kept quiet and in bed, in a room where there are no other children. The crib should not be in a corner of the room or against the wall, but should be accessible from all sides without being in a direct draught from a door or window. The air supply is better, it is easier for the nurse to change the child's position, give medicine, or use steam if the cot be away from the wall. Counter-irritation to the chest by means of a mustard paste, 1 part mustard to 4 or 5 of flour, or a mustard bath at a temperature of 95°–100° F. will loose the labored breathing, lessen the congestion, and calm the nervous system. Early stimulation to the chest is never to be overlooked, but care must be taken that the delicate skin of the infant is not blistered. The first evidence of the rapid breathing and cyanosis calls for oxygen and it does greater good than when administered late in the disease. The oxygen is to be given freely and its effects noted. Poultices are not to be applied, as their weight and the need for constant renewal are reasons why they are harmful in a disease that is protracted and accompanied by weakness and depression. Jackets of flannel and of flannel and oiled silk are much better than poultices, as the skin under them can be cleansed.

Steam alone or with oxygen will prove of service in many cases, but to envelop a child with steam until the skin is covered with moisture is not conducive to comfort or well-being. The steam is to be given for a few minutes at a time when the breathing is difficult or when the mucus secretion is tenacious and expectoration is troublesome. The vapor is to be directed under a tent by means of a tube and funnel. In some instances the addition of compound tincture of benzoin seems to be soothing. Turpentine will aid a slow resolution.

The diet is to be the best that can be provided, not so much in quantity as in quality. An infant at the breast should have the natural supply, supplemented as need be by a few drops of beef-juice, peptonoids, and egg water. Older children should be fed peptonized or diluted milk, cream with water, soups, meat jellies, custards, beef-juice, scraped beef, and such other foods as can be given in small quantities without distending the stomach and intestines or adding to a catarrh of the enteric tract. Water is always allowable and patients should have plenty of it. As bronchopneumonia is a protracted disease the management of the diet deserves more thought than the average physician bestows upon it. Forced feeding is to be tried when other means fail.

Children who are flatulent and whose movements are fetid and contain mucus are relieved by intestinal irrigation with a normal salt solution. The effect of the solution is beneficial in cases in which the pulse is poor and the vitality low.

Baths and wet packs are to be used to reduce temperature, and a bath at 95° F. gradually reduced to 85° F. with friction will do more good than any other antipyretic. The pack at 65° to 70° F. is often the best means to reduce temperature and lessen the nervous symptoms of a pneumonia. The effect on the peripheral circulation is better than a bath at a higher temperature.

The medicinal treatment of bronchopneumonia is

not always satisfactory, but there are drugs that are valuable and their use must not be omitted. In the early stage, when there is a general bronchial catarrh, a few doses of castor oil given in an emulsion with a small quantity of ipecac will clear the air-passages of mucus and move the bowels. Calomel is a drug that has a decided effect in many cases when the digestion is interfered with and the liver is engorged.

Codein in $\frac{1}{16}$- to $\frac{1}{4}$-grain doses will lessen restlessness and troublesome cough early in the disease, but at times the camphorated tincture of opium will be the best preparation of opium to give. Nitroglycerin has an important place in the treatment of pneumonia, and is indicated when the heart's action is weak, with pale skin and poorly filled arteries. Without doubt it lessens the pressure in the right heart. It is to be given in doses of $\frac{1}{600}$ to $\frac{1}{100}$ of a grain. Strychnin, preferably the nitrate, is a valuable agent and its use for a weak heart struggling against the pulmonary engorgement is satisfactory and life-saving, but its action on the nerve-centers is to be remembered or else a child will have symptoms not due to the disease. Strychnin should be given in solution in doses of $\frac{1}{600}$ to $\frac{1}{60}$ of a grain, and it should be administered hypodermically if the emergency demand it. Digitalis, strophanthus, and caffein have their places as heart stimulants, but are not so valuable as strychnin and nitroglycerin.

Digitalis steadies the heart, but it contracts the arterioles and its value depends more upon its effect on the systemic than on the pulmonic circulation. Whisky and brandy are needed in most cases of bronchopneumonia, not always early in the disease, but when the inflammation is lessened and vitality is low or when there is atelectasis. They are not to be given as a routine treatment in all cases, but most children will do better if alcohol is administered at some time during a lobular pneumonia.

The aromatic spirits of ammonia in doses of 10 or 15 drops added to water will help expectoration and prove a suitable stimulant when alcohol in other forms is not used. Creosote is a valuable drug in the pneumonia of children whose history is tubercular or when there is free purulent secretion. Late in the pneumonia it is beneficial when continued with cod-liver oil. Creosote in ½ to 1-minim doses or given as the carbonate in 2 to 8-drop doses is a good cough mixture if used with a thick malt extract. Cod-liver oil has an important, dual position in the treatment of pneumonia in children. It is often the fat food that is required and the disease is lessened in severity by its use. I do not hesitate to administer it in every case in which the digestion is not impaired or the temperature high. Cod-liver oil will lessen the severe cough of a long-continued pneumonia and it is of service when given with creosote and whisky. Quinin is helpful in more cases in which the disease is protracted with an irregular temperature than in those with pertussis. The iodid of iron and the hypophosphites are not to be forgotten in the exhaustion and weakness of a protracted convalescence.

Antipyretics of the coal-tar class, cough mixtures with emetics and nauseating drugs are best omitted. Young children do not expectorate, and syrups with expectorants only derange the stomach. Special indications for drugs are to be met as they arise, but the most satisfactory results in the treatment of pneumonia complicating measles will come from the careful nursing and feeding of the patient and the administration of remedies that will add strength and resistance to stop the advance of the invading micro-organism.

HYDROTHERAPY IN THE PNEUMONIA OF CHILDREN.

BY SIMON BARUCH, M.D.,
OF NEW YORK.

HYDROTHERAPY in the treatment of the pneumonia of children being assigned to me for discussion, I shall confine myself strictly to this branch of the subject and omit all reference to other measures, such as absolute rest and isolation, careful nursing, perfect ventilation, and feeding. These are quite as important as, and often more important than, hydrotherapy.

The guiding principle in the treatment of the pneumonia of children should be to *treat the child and not the disease.* Until we possess an antitoxin it is wise not to follow the practice of the past, the object of which was to throttle the disease by bleeding, blistering, veratrum, antimony, quinin, etc.; nor to follow implicitly the expectant practice of the present, which meets the symptoms of high temperature, heart failure, etc., as they arise and provides chiefly for a comfortable passage through the ordeal.

The mission of the modern physician is the same to-day as it was in the day of the great Nestor of Medicine, Hippocrates, and as enunciated by the philosophic Esclepiades and his disciples, *to aid the vis medicatrix naturæ* by endowing the system with all possible strength to enable it to struggle successfully against the lethal tendencies of disease.

The dangers in the pneumonias of children are: (1) Toxic contamination of the nerve-centers. (2) Respiratory embarrassment. (3) Cardiac adynamia. Among the remedial agents which have been assiduously plied to meet these dangers the judicious use of water stands easily foremost. This statement

is not only based upon my personal observations but it is confirmed by the great pediatrists of Germany and France. Baginsky writes that "the chief aim of treatment is to moderate fever and maintain the strength and that both indications are well fulfilled by cold compresses which are life saving." Penzoldt analyzed 2200 cases of pneumonia in children, and from this enormous material concluded that "preference should always be given to a cautious bath treatment." Le Gendre writes, "This method is of especial value in infantile therapeutics; it may be used for the youngest child." Hutinel says: "Patients who have been bathed 'return to life.'" Strong commendation this, which I might multiply, if time permitted. Our own Jacobi favors this treatment also, as you all know, in pneumonias with high temperature.

No remedial agent is entitled to acceptance, however, if its action be not explicable by sound reasons. What is the rationale of the action of cold-water applications to the skin in pneumonia? A contraction of the cutaneous vessels ensues, followed by an active dilatation, which furthers the flow of blood through that enormous vascular area of the skin, which it is said is capable of holding from thirty to fifty per cent. of the entire blood of the body. What is the result? The heart is relieved of much of its labor and all the functions depending upon an unembarrassed circulation are promoted. It has been shown by reliable experiment that in rabbits poisoned by injections of pneumococci the vasomotor center in the medulla is depressed and the peripheral vessels are thus relaxed and become passive. Instead of actively participating in the propulsion of blood as is their normal wont they now permit it to passively flow through them favoring engorgement and throwing additional work upon the heart which is already embarrassed by the toxins circulating in the blood and probably also by high temperature. Increase in rapidity and diminution of tension are the result, enhancing the existing pulmonary engorgement, increasing dyspnea, diminishing excretory activity and thereby promoting retention of toxins which sooner or later overwhelm the nerve-centers, elevating the temperature and which start the vicious circle anew. We have no medicinal agent upon which we can rely to overcome this vasomoter "paralysis."

The application of cold water to the skin arouses a neurovascular excitation which is transmitted to the central nervous system from which it is conveyed to the heart, increasing the ventricular force, with a better filling of the arteries; to the lungs, deepening inspiration, with an improved expulsion of accumulated secretion; to the skin, favoring heat diffusion and reducing temperature; to the kidneys, increasing enormously the quantity and toxicity of the urine. In fine, the disturbed machinery of the sickened organism is started into a more normal activity; its conservative mission is resumed; the *vis medicatrix* is raised from the slough into which the disease has cast it. Theory and practice combine, therefore, to attest the value of water as an agent to fortify the organism against the onslaught under which it is staggering. Being a two-edged sword, it is of paramount import that water be applied with judgment and discrimination, according to the exact demands of each individual case, and that its use be continued without fear or favor, unless some contraindication arises.

Time will permit me to offer only a general outline of the hydriatic procedures which I have found useful and to inculcate the necessity of using each with due regard to its rationale. In children under three years, the tub bath with continuous friction is most useful. If the body temperature is between 101° and 103° F. a tub is placed upon two chairs, near the bed; it is half filled with water at 95° F. The child's face is now bathed with water at 75° F., and its trunk is gently submerged and held by pressing the fingers upon one shoulder (not upon the chest). Ice-water is now added, without being allowed to touch the child's body, until 85° F. is reached; friction over the entire body is maintained for five minutes.

This is a good initiatory procedure; it may be repeated every four to six hours with advantage so long as the temperature does not fall below 101° F. When the body temperature is above 103° F. the bath water may be reduced to 80° F., very rarely lower, and never so low as some bath temperatures mentioned here this evening. The duration should be prolonged to eight minutes; in this event it requires repetition every four hours. In the intervals between the baths a compress, covering the entire anterior part of the trunk, consisting of three folds of old linen or a towel (without fringes), wrung more or less out of water at 70° F., and secured by a flannel bandage placed around the body, may be applied with advantage every hour when the patient is not asleep. This procedure not only fulfils every indication but it also renders the demand for bathing less frequent. When delirium and stupor are present, when cyanosis is pronounced, and cardiac action embarrassed, when the bronchi are clogged with secretions, increasing dyspnea, in these conditions, which are so frequent in bronchopneumonia of children, the full bath may be changed to dips into water at 80° F. or less for a few seconds, repeated two or three times in rapid succession every hour,

the temperature, duration, and frequency being in accord with existing conditions. An excellent procedure in these desperate cases is the affusion with basins of water at 60° F. or less poured over the head and shoulders of the patient, who is held semi-recumbent in a tub containing water at 100° F. Rapid drying and friction are demanded after these procedures, because the patient's reactive capacity is below par. Body temperature is not an index for the cold affusion, which should be given in these desperate cases even if the temperature is low. We aim to stimulate the central nervous system and thereby improve the circulation, respiration, and expectoration. When the child is restless, an occasional full bath at 95° F., prolonged for ten minutes, will prove soothing.

In most children over three years of age full baths are too disturbing. A younger child will become quiet as soon as it experiences relief and comfort, while the older child will continue to struggle and scream. Whenever the child is tractable I prefer the full bath, but I insist upon it in every case when other treatment proves inadequate. Having observed that the toxins of pneumonia endow the patient with less resistance to cooling procedures than do the toxins of typhoid fever, I avoid full baths colder than 75° and longer than eight minutes in the former disease. In the management of pneumonia patients larger reductions of the body temperature are not the prime object.

In most children above three years of age the chest compress, consisting of three folds of old linen so arranged by slits in the axillary portion as to fit snugly around the chest down to the navel and held in position by a flannel binder, is the most useful procedure. The linen is wrung out of water at 65° to 70° F., more or less thoroughly, according to the temperature and general condition, and the flannel bandage is pinned over it. (Oiled silk, which the nurse will recommend for protection of the bed, counteracts the object of this compress and converts it into a poultice.) It is repeated every hour and discontinued when the temperature reaches 100° F.

These are the simplest and most useful hydriatic procedures in the pneumonia of children. The time limit precludes their more detailed description.

Let me conclude with a few words of warning. Spontaneous reaction must always be provided for by friction *during* the bath so that there should be no need for warmth and friction *after* the bath. Whenever the patient becomes very chilly, with chattering teeth and cyanosed face, we may conclude that the procedure has been faulty and must be modified. A few nights ago I saw a case in consultation with a well-informed practitioner who feared water-treatment because the patient had become cold and cyanotic under a wet-pack. Inquiry elicited the fact that the patient had been simply wrapped in a cold, wet sheet (no definite temperature). She was not covered snugly by blankets, as is demanded by the technic of the wet-pack in order to promote reaction. This incident illustrates the importance of correct technic. Reaction is always furthered by rubbing during the procedure, or by protection against evaporation. It may be enhanced, also, by modifying the temperature of the water, not, as is often erroneously done by elevating it, but by lowering it within reasonable limits, and shortening the procedure. It is a law of hydrotherapeutics that low-water temperature, strong mechanical impact, and brief duration promote reaction. Higher bath temperatures are more agreeable and, if the procedure be prolonged, afford greater temperature reduction but do not produce the stimulating, antifebrile effect of a correctly adapted cold procedure.

Hippocrates has said: "Cold water stimulates, warm water depresses," and yet these important truths still remain to be taught to-day. Thus is demonstrated the crying need of instruction in hydrotherapy in our medical colleges. The internal administration of cold water plays an important part in the treatment of pneumonia as of all infectious diseases. It is refreshing, vivifying, promotes secretions, and aids in increasing the quantity and quality of the urine. One to four ounces, according to the child's age, should be given systematically every two hours, alternating hourly with milk. Cold water must be administered with the same regularity and noted on the nurse's report with the same precision as is medicine.

General Discussion.

DR. F. M. CRANDALL: There is no subject upon which medical men disagree more than upon that of the treatment of disease, and this is particularly the case in regard to the treatment of pneumonia; yet from what we have heard here to-night we must recognize the fact that in the great essentials opinions are very similar, and that the principal points are pretty well settled. For example, we are fairly well agreed that drugs form a very slender reed upon which to lean in the treatment of pneumonia; that is, those of us who see a great deal of pneumonia have come to this conclusion, for I do not think that this can be said of the profession at large. From what I have seen and heard shot-gun prescriptions are still employed, and I think that though pneumonia has killed many children, drugs have killed a great many more. Of course, there are some drugs which are employed by all of us, such as strychnin, nitroglycerin, and alcohol, but the indications for these are pretty definitely laid down,

although there is some difference of opinion in regard to the remedies to be used to control the nervous symptoms and restlessness. Other points upon which we seem to be agreed is that children suffering from pneumonia should be kept very quiet, and that careful attention must be given to the diet. As Dr. Holt has pointed out, many children suffer harm from the constant attempts to do something for them. In a case which I saw last winter the child was getting something every half hour during the day and every hour during the night, and was suffering as much from loss of rest as from the pneumonia. We must not forget, moreover, that in private practice many of these cases of pneumonia are self-limited and tend to recovery. In this they differ from those seen in hospital practice. The ordinary vigorous child who contracts pneumonia is more likely to recover than he is to die. As little medicine as possible should be given in these cases, and many recover when none is given. The diet is the principal thing. Many of these patients are improperly fed during the early stages of the disease. In the beginning there is high fever, and the child will drink anything which is given to him. If much milk is given at this time the stomach will soon rebel, and an acute indigestion, which will retard recovery, will follow. As the disease progesses the child loses his appetite, and it then becomes very difficult to get him to take sufficient nourishment. Food at regular intervals should be prescribed and its administration insisted upon.

In treating pneumonia in hospital practice I rely largely upon inhalation of steam under a tent, and upon mustard-paste. The latter is of great service, but should not be left on too long. It is easily applied without exposing the patient, and in my experience has been followed by prompt results. In some cases in which it was discontinued the nurse or mother asked to have it reapplied because of its quieting effect upon the child.

DR. W. P. NORTHRUP: The first essential in the treatment of pneumonia is an accurate diagnosis. It is not uncommon to see cases in which the cerebral symptoms have been treated by a liberal use of the ice-bag under a mistaken diagnosis. This is epecially apt to be the case when the center of the lung is the seat of the pneumonia. In other cases a diagnosis of malaria has been made. After pneumonia has been diagnosticated the prognosis should be considered, and it should be remembered that this is usually very good in the ordinary, unplicated form of the disease which is not preceded by measles, whooping-cough, or grippe, unless the attack is extremely severe. Little treatment is necessary in most of these cases, but whatever you do, do not put a child with a temperature of 104° or 105° F., and respiration at 60 in a hot poultice tightly wrapped about its chest. Particular attention should be paid to the condition of the digestion and the diet. Fresh air is also an essential. The restlessness and nervous symptoms should be relieved by the cold pack, care being taken to keep the extremities warm by means of hot bottles.

DR. BERG: It is rather unfortunate that the term pneumonia has been applied to two conditions which are radically different, especially as to prognosis and treatment. Lobular pneumonia is entirely different from croupous pneumonia, the latter being of but little importance, and the prognosis and treatment depend absolutely upon the differential diagnosis. We are all familiar with the frightful picture presented by croupous pneumonia on the second or third day before the crisis, and yet we know that these patients usually recover. On the other hand, a child suffering from bronchopneumonia looks well, and may die a few hours after you have said that he was improving. Some of the speakers have made an effort to separate the two types of disease, but this differentiation should be emphasized in every part of the discussion. Children recover from croupous pneumonia under any treatment, even under the old-fashioned poultice treatment, which is the most barbarous I know of, whereas the treatment of bronchopneumonia requires the greatest skill, the most careful therapeusis, and the closest watching on the part of the physician.

During the discussion I noticed that the use of the poultice has been but slightly recommended in the treatment of either form of pneumonia, but I was sorry to hear one of our best authorities mention favorably the use of the oil-skin jacket. I have always looked upon this as a thin, light poultice. Both should be avoided in the treatment of pneumonia. Another of the speakers, in referring to the coal-tar group of drugs, said that small doses of antipyretics seem to reduce temperature in children suffering from pneumonia; that not only is there no objection to using these drugs, but that it is desirable to do so in cases in which nursing facilities are lacking. In my experience I have found that these small doses have absolutely no effect in the vast majority of cases. Large doses, fortified by digitalis, are followed by reduction of temperature, but this is a very dangerous therapeutic measure. If there is any one group of drugs which medicine would have been well without, that group is the antipyretics. Chemistry has done practical therapeutics great injury by the development of these drugs. In spite of their value as antispasmodics and in the neuralgias, we would be better without them, for their use has been greatly abused by the ignorant practitioner of medicine. There is one drug, however, which I have found of great utility in bronchopneumonia, and that is the sulphate of quinin, given in small doses, and in powder with sugar of milk.

There is a method of treatment devised by Dr. Seymour of Troy which deserves a trial in cases of bronchopneumonia. It consists in raising the foot of the bed some eighteen inches higher than the head in order that gravitation may aid in getting rid of the secretions. The excellent results which have followed this method of treatment in cases of diphtheria, and after tracheotomy would lead one to think that it can be employed with advantage in bronchopneumonia.

One word in regard to opium in pneumonia: It is a mistake to stop the cough of bronchopneumonia in children. Nature has made the cough a safeguard to prevent extension of the disease; if you stop the cough you remove one of the means provided to make the disease a limited pneumonia.

CLINICAL MEMORANDA.

A CASE OF CHLOROFORM POISONING.

By DAVID TRUMBULL MARSHALL, M.D.,
OF NEW YORK;
ATTENDING PHYSICIAN TO THE HOME FOR THE AGED.

MRS. M., a trained nurse forty years old, the mother of two children, weight about 120 pounds, had never been ill except that for two years she had had gastritis, with occasional attacks of colic.

After eating a night luncheon, consisting of tea, toast, and a small quantity of canned salmon, she was seized with very severe pains in the stomach of a colicky nature. She took a tablespoonful of tincture of ginger and applied a hot-water bag to the abdomen, but without relief. She then took 10 minims of chloroform in a little water, which relieved her for a time. On the return of the pain she took another 10 minims, and followed this by a third dose of 20 minims—40 minims in all.

About this time her room-mate noticed that she was acting strangely and sent for me. The chloroform-bottle and minim-glass were standing on the table when I entered the room. The testimony of the woman's room-mate and the odor of chloroform on the patient's breath were enough to establish a working diagnosis. The patient was lying on the bed in a semi-conscious state. On attempting to rouse her she spoke incoherently and begged to be left alone. Her pulse was very slow and irregular and her respiration slow and sighing, at times stopping altogether, but starting again after vigorous slapping of the chest.

I seized my medicine-bag and took from it a full four-ounce bottle of a heart stimulant, containing in each dram, strychnin sulphate, $\frac{1}{30}$ of a grain; tincture of digitalis, 2 minims, and whisky, 1 dram. Of this I injected hypodermically 30 minims and repeated the dose *nine* times in the course of an hour and a half, thus aggregating, strychnin, .22 grains; tincture of digitalis, 9 minims, and whisky, 4.5 drams. After each injection the patient rallied for a moment and then relapsed into an unconscious state. On several occasions respiration ceased entirely and the heart-beat was almost imperceptible. In addition to the hypodermic medication the patient's face and chest were bathed with cold water and the chest was slapped frequently with a wet towel. Artificial respiration by Sylvester's method was resorted to and the feet were bathed with hot water. Later, when more help arrived, the faradic current was made use of, applications being made over the chest and heart. This evidently caused great pain for she begged to have it stopped whenever she had a lucid interval. Toward the end of an hour she showed signs of strychnin poisoning —*risus sardonicus* and spasmodic respiration. This became very marked so that I feared to give any more of the drug until she began to relapse into unconsciousness again, when, having nothing else at hand, I was compelled to inject more strychnin. At the end of two hours the effects of the chloroform subsided. It was nearly two days before the patient recovered from the effects of the drastic measures instituted to save her life.

In regard to the correctness of the amount of chloroform taken I am confident there is no mistake, for the patient, who was an unusually careful woman, told me afterward that she measured it carefully, but had confused the dose of chloroform (2 to 5 minims) with that of ether (5 to 60 minims) and thought she was taking a safe amount.

MEDIAN CERVICAL FISTULÆ.

By F. HUBER, M.D.,
OF NEW YORK.

BRANCHIAL or lateral cervical fistulæ are fairly frequent and always congenital. Median cervical fistulæ, on the contrary, are rare and never congenital, though due to an abnormality in the thyrolingual duct. One of three anomalies may be the result of imperfect obliteration of this fetal channel: (*a*) lingual dermoid; (*b*) median cervical fistula; (*c*) accessory thyroid. At the present time, we are only concerned with the abnormality arising in the thyroid portion of the duct, giving rise to a median cervical fistula. Such openings occur singly at some point in the median line between the hyoid bone and the sternal notch, usually about the level of the cricoid cartilage. In some instances a firm cord can be felt running up in the direction of the hyoid bone. They may occur soon after birth or not until the fourteenth year; in one of my cases not until the nineteenth year. They are always preceded by a swelling in the median line, usually about the size of an almond or hickory-nut, which may become tense and inflamed, and ruptures, or is opened by the surgeon. The sinus left is intractable, discharges a glairy mucus and, when explored with a probe, is found to run up in the direction of the hyoid bone or even behind it.

Bland-Sutton gives a brief account of a case reported in an able paper by Dr. C. F. Marshall, which established in a satisfactory manner the nature of these fistulæ. In view of this, they must be regarded in the first place as retention cysts formed in a persistent thyro-glossal duct.

The first case coming under my care was in a male, about nineteen years old, who as long as he could remember had noted an almond-shaped swelling in the median line over the thyroid cartilage. It was painless, with no evidences of inflammation, had not increased in size, and was only a source of discomfort because of annoyance due to contact with his shirt collar. It was laid open by a vertical incision, the interior cauterized with pure carbolic acid, and packed with gauze. The greater part disappeared and left a tortuous sinus running up to the hyoid bone, discharging now and then a few drops of glairy mucus. When the cyst was incised in the beginning, the same glairy mucus escaped, similar to what is found on exploring a "weeping ganglion."

The true nature of the trouble was not suspected until later. At first it was regarded as a bursa. The intractable character of the sinus, and its direction as determined by probing, revealed its true character. It persisted for more than a year, but after repeated cauterizations finally closed. There has been no recurrence for nearly two years.

Case No. 2 occurred in a child about three years old.

There was a history of a median swelling of the neck, which ruptured and left a tract running upward toward the hyoid bone, and discharging a glairy mucus at times. A thickened cord could be felt, corresponding to the sinus referred to. Operative measures were refused and the child passed from under my observation. A further point of interest was the occurrence of an occipital dermoid in an older sister.

The interesting case reported by Scudder of Boston in the MEDICAL NEWS of September 24, 1898, undoubtedly belongs to the same category. The history, the character of the discharge, the direction of the sinus, etc., all favor this view.

MEDICAL PROGRESS.

Delivery of the Placenta after Abortion.—It is often a difficult task to remove the placenta from the uterus after abortion. BUDIN (*L'Obstetrique*, September 15, 1898) accomplishes it by placing one or two fingers as high up in the posterior cul-de-sac as possible, making pressure with the other hand upon the fundus of the uterus. In this manner the organ is grasped between the two hands and the placenta can usually be expelled without difficulty. If the os is only large enough to admit one finger it facilitates matters to insert the forefinger and break the placenta up into two or three parts before expelling it. It should, in all cases, be completely separated from the uterine wall, but this is accomplished without difficulty.

Stiff Neck and Lumbago.—ERBEN (*Centralb. für Chir.*, September 10, 1898) says that in twelve cases of rheumatic stiff neck which he investigated the sternocleidomastoid was either unaffected or was secondarily involved. The position of the head was taken to relieve the pain, not on account of muscular contraction. The lesion was situated in the joints of the convex side of the neck or in the nerves coming out between them. A similar explanation was given for lumbago. Erben examined 200 patients suffering with this trouble. In no one did he find the muscles to be affected. In 119 cases the joints of the lumbar vertebræ were affected. They were painful on pressure, and pain prevented lateral flexion and a concave bending toward the sound side. In twenty-one cases there was a neuralgia of the nerves of the skin.

Gastric Fermentation.—TALMA (*Zeit. f. klin. Med.*, vol. xxxv, p. 542) insists on the great importance of the gastric fermentations which result from undigested starches and sugars. He says that fermentation is the cause of motor insufficiency of the stomach, and that the latter will usually disappear as soon as carbohydrates are withheld from the diet. The motor insufficiency can cause pyloric spasms. Fermentation is one of the causes of excess of hydrochloric acid. The spasms excited by the fermentation and the strong acids can produce ulceration of the stomach and perhaps perforation. Out of ulceration carcinoma may develop. His treatment is a simple one, and consists in withholding carbohydrates until all symptoms have subsided. Many patients if put upon raw eggs, eighteen or more in the twenty-four hours, together with oysters, butter, chopped meats or boiled fish, will recover their health in a short time. In many instances the motor insufficiency and excess of hydrochloric acid disappears in a day or two. Patients with carcinoma of the stomach on this diet get on comfortably until they near their end. Then anything will cause distress which is not absolutely bland in temperature as well as mechanically and chemically unirritating. At this period even meat and soups have to be given up, and the patient subsists upon raw eggs and water until a gastro-enterostomy is performed. Usually all signs of fermentation disappear in two weeks, but in order to prevent a recurrence of the trouble it is necessary to limit the amount of carbohydrates which are permissible for a year or two.

Percussion of the Pulmonary Apices.—OESTREICH (*Zeit. f. klin. Med.*, vol. xxxv, p. 491) has demonstrated the possibilities of an exact percussion of the pulmonary apices by the examination of a large number of subjects post-mortem. He found that the conditions for percussion were substantially the same upon the dead as upon the living, and the former offered the tremendous advantage of allowing an immediate verification of the findings. In this manner he ascertained that a single nodule of consolidation in the apex had to reach the size of a cherry before its presence could be shown by percussion. If smaller than this it could not be recognized, even though it was situated upon the pleura. But if there were several nodules close together they could be detected, even though the individual nodules were much smaller than a cherry. No reliance could be placed upon opinion as to the situation of nodules or their exact size. All that could be determined was the presence or absence of consolidation in a given apex.

Oestreich found that he could obtain far more delicate results by percussion with one finger upon another than he could by using a hammer and pleximeter. Skill in making an exact diagnosis by percussion varies with the individual, but is greatly increased by practice. Attention is once more called to the fact that tubercle bacilli grow in the lung for a considerable time before the ulceration of the mucous membrane results in their presence in the sputum, so that there is often an area of consolidation readily distinguishable by percussion when the sputum is absolutely free from the bacilli. Hence the "negative examination" of the sputum is not by any means proof that tuberculosis of the lungs does not exist. In every case of beginning phthisis of the apex there is a diminution in size of the affected pulmonary tissue, which can be made out by very light percussion. For nodules sometimes the percussion needs to be strong so that the examiner is cautioned not to fall into the habit of percussing only with a light stroke. When the affected tissue becomes diseased and shrinks there is an increased distention of the surrounding tissue, so that a slight tympanitic note results. From these two factors result the dull, high-pitched resonance which is noted on the affected side. Oestreich also demonstrated the accuracy of percussion of dead bodies by successfully locating cavities, pleuritic effusions, pneumothorax, isolated air-

spaces in the abdomen, increase in size of the different chambers of the heart, hydropericardium, and variations in the size of the liver and spleen, thus showing that the method is as accurate after death as before.

THERAPEUTIC NOTES.

The Radical Cure of Spina Bifida.—NICOLL (*Brit. Med. Jour.*, October 15, 1898) believes that any case of spina bifida may be operated on with a fair chance of success. If the neck of the sac is small it is sufficient to pass a ligature about it. In larger sacs he employs rows of catgut suture. Long flaps of skin and mesoblastic tissue are used to close in the gap. The sutures are applied in such a manner that the redundant margins of the mesoblastic flaps are curled inward just as the cut margins of intestine are curled inward by a Lembert suture. The skin is sutured in a similar manner but its edges are turned outward. The ridges thus formed in the median line add to the strength of this posterior covering of the spinal canal. Of thirty-two patients operated upon twenty-five recovered. In some of the fatal cases hydrocephalus was associated with the spina bifida.

Treatment of Hydrocephalus by Intracranial Drainage.—SUTHERLAND and CHEYNE (*Brit. Med. Jour.*, October 15, 1898) employed intracranial drainage in three cases of hydrocephalus, acting upon the theory that the distention of the ventricles is due to the closure of the channels of communication between them and the subarachnoid spaces. Fluid cannot collect under pressure in the subarachnoid spaces since they are in communication with the veins. The two lateral ventricles usually communicate freely in hydrocephalic children so that it is considered sufficient to establish drainage on one side of the brain. The first patient so operated upon was an infant six months old with congenital progressive hydrocephalus. Sixteen strands of fine catgut were tied together and were used as a drain from the ventricle to the subdural space. A very small opening was made in the dura and both this and the incision in the skin were closely sutured. The child recovered from the operation, the wound healed perfectly, the head diminished rapidly in size, but there was no improvement in the child's mental condition, and in three months it died of basilar meningitis. A second patient operated upon also recovered from the operation but the head diminished in size upon the operated side only. Three months later the side not operated upon was still much distended showing that communication between the ventricles had ceased. Accordingly a second operation was performed upon that side and with entire success. The child improved physically but showed no evidence of mental development. Another patient twelve months old was operated upon in a similar manner without success. The second operation was performed, but before any possible good effects had time to manifest themselves the child died of measles with complications.

The Value of Fasting in the Treatment of Acute Infectious Diseases.—DOMINICIS (*Centralb. für Inn. Med.*, September 10, 1898) as a result of his own investigations concludes that fasting within certain limits increases both in men and in animals the power of resistance to microbes and their toxins. The reason lies in the fact that any form of nourishment, even milk, undergoes a putrid fermentation whenever the digestion is not perfect and the toxins which result from this so alter the tissues and fluids of the body as to weaken their resistance to bacteria. The favorable influence of fasting and disinfection of the gastro-intestinal canal has been abundantly proved clinically, especially in cases of pneumonia.

Treatment of Migraine.—KOVALEWSKY (*Rev. de Therapeut.*, October 1, 1898) recommends the following prescription in the treatment of migraine:

Sodii bromid.	℥ ii
Tr. strophanth.	℥ ss
Cocain. hydrochlorat. . . .	gr. iss
Aq. aurantii	℥ vss.

M. Sig. A tablespconful three times a day.

This medicine should be taken at intervals for a period of two years. If the patient is alcoholic, tincture of nux vomica may be substituted for the cocain. When the pain is very bad the following prescription may be given in divided doses:

Caffeinæ	gr. ivss
Phenacetin	gr. xxii
Antipyrin	gr. xv
Antifebrin	gr. xxii.

SARACON, in the same journal, recommends the mechanical treatment of migraine by an apparatus like a double spring truss for hernia. Two pads are placed upon the temples which they compress with considerable force. He claims to have had satisfactory results from the use of this instrument.

The Treatment of Insanity from Traumatism.—HARRISSON (*Liverpool Medico-Surgical Jour.*, July, 1898) describes four cases of insanity following fractures at the base of the skull, one following bullet wound of the brain, and three following blows upon the vault. It is a mistake to consider a patient out of danger as soon as a wound in the skull is healed. Such patients may develop insanity as a result of the depression of the skull or splinters of bone, or from a thickening of the bone, or from cysts. Seventy-seven such cases have been recorded, in which operation was performed for the resulting insanity, and of these only 7 patients had been operated upon immediately after the accident, although in 48 symptoms of depression were present. It is interesting to note that in only 4 of these 77 cases was the dura opened. This shows that an operation of this character is comparatively safe, while the improvement which follows in many instances is extremely gratifying.

Of the 77 reported cases, 5 deaths occurred. Of the 57 cases reported in the last 17 years, only 2 patients died. Of mental recoveries, 51 are reported; of great improvement, 12 cases; of slight improvement, 5 cases; no improvement, 4 cases. Of these 4, 2 patients showed temporary improvement before relapsing, and in 1 there had been no local indication for operation.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK,
AND NOS. 706, 708 & 710 SANSOM ST., PHILADELPHIA.

SATURDAY, NOVEMBER 19, 1898.

WE present this week the symposium of eminently practical papers on pneumonia in children, which were read by well-known authorities on children's diseases at a recent meeting of the Section on Pediatrics of the New York Academy of Medicine. It is an extremely timely subject, and we feel sure will be thoroughly appreciated by our readers. Of special practical interest to the general practitioner is the stress that all those who took part in the discussion of the subject laid on the necessity for fresh air in the sick room. With the old prejudices as to drafts, etc., that are still so strong, fresh air is one of the hardest things to secure in the management of pneumonia in private practice. The suggestion that there be a second room into which the little patients should be carried for several hours each day while the ordinary sick-room is being thoroughly aired deserves to be kept in mind in all cases.

More and more is the realization coming that in all lung troubles fresh air is the most important factor in therapeutics, and that the rebreathing of air, the inhalation of organic products of respiration, is apt to be serious in its consequences. In the treatment of pulmonary tuberculosis this is the dominating idea at present. How important it is considered to be in pneumonia cases, in Europe, may be judged from the fact that in many of the large teaching clinics a pneumonia patient is kept but a few minutes at most before the class, unfortunate experience having shown that patients kept for any length of time in a crowded clinic-room are very apt to have a turn for the worse, a retarded or incomplete crisis, or some complication that his condition before presentation to the class gave no reason to anticipate.

DURING the past few years one has read now and then of a new sect of healers calling themselves osteopaths who profess to cure disease "by utilizing the system of drugs which the body has within itself to cure all infirmities," but probably few physicians realize that the form of paranoia which osteopathy stands for is spreading so rapidly that it bids fair to become a menace to personal safety, as well as a public nuisance. It has now a number of so-called colleges in which it is said that candidates study, are graduated, and are taught to believe that "a loving, intelligent Maker of man has deposited in some place in this body or through the whole system drugs in abundance to cure all infirmities, which can be administered by adjusting the body in such a condition that the remedies may naturally associate themselves together, hear the cries, and relieve the afflicted." These are scattered throughout the country, principally in the West, and their doctrines are disseminated by several journals of osteopathy which circulate in every part of the land. The fact that osteopathists have been able to so influence legislation that their right to practise is legalized in a number of States, such as Iowa, North Dakota, Michigan, Illinois, North Carolina, and even Vermont, shows that the sect has already become a facultative saprophyte. Although the Empire State has very stringent laws regulating the practice of medicine within its confines osteopathy flourishes here, as witness a recent article in the *Cosmopolitan Osteopath*, which states that Dr. ———, who five years ago was a traveling "drummer," now enjoys the distinction of having the largest and most lucrative practice of any graduate in the science (sic) of osteopathy now practising the profession. Some idea of the constitution of the osteopathist's clientele may be gathered from the

statement that among the regular patrons of one of its practitioners in New York city during the past year was the chief dignitary of the Protestant Episcopal Church in this State.

That the disciples of this most senseless and grotesque of all healing cults take themselves seriously is shown by the fact that a contemporary, the *Medical Age* of Detroit, has been sued for $25,000 damages by one Dr. William Smith, Osteopathist, of the *Journal of Osteopathy*, to cover the injury that has been done him by an editorial which appeared in the *Medical Age* reflecting on osteopaths generally and on the above-mentioned osteopath particularly. Although we must confess our entire ignorance of Dr. William Smith's history we feel quite safe in hazarding the guess that he has at least heard of a game called poker in the successful playing of which bluffing has a very conspicuous part. The player who calls the bluff, however, pockets the cash. Dr. William Smith, Osteopathist, is putting up a big bluff, but the proprietor of the *Medical Age* has called him very promptly, and in a way that augurs ill for the hypersensitive bone-sufferer. Our advice to him is to place himself under the care of some brother osteopath who should apply himself to discover what "slight displacement of some bone is causing obstruction to the flow of one of the fluids of his body" (as this is one of the props on which their "science" is founded) to account for his erethism. The *Medical Age* is abundantly able to take care of itself and we need hardly assure it that it can count upon the moral support and commendation of the medical profession and its representative journals.

SOCIETY mamas seem to be considerably exercised (as indicated by the unrestrained expression of opinion at the recent meeting in New York of the Association of Women's Clubs) over the fact that the duties of the modern trained-nurse sometimes give her opportunities of making herself agreeable to the modern young man in a way that at times leads to matrimony. Some of the mamas even ventured to hint that it is with a sense of trepidation that they see their sons take up the duties of hospital internes, where for a year or more they are to have no feminine mentor to guard them from the wiles of "taking" nurses, and are to be the legitimate prey of designing femininity in the fetching cap and gown of nursedom.

The dear, fond mamas have our sincerest sympathy, but if their matrimonial plans for their young hopefuls suffer shipwreck because some siren has proved too attractive on the voyage of life, long before the vessel freighted with their hopes comes to the port they wished for, we must remind them that there have always been sirens, and that even when Homer wrote, the story was as old as the seas. For the young doctor we have no message in the matter, not even a bit of advice, but we hope that our continence will be properly appreciated; for when a man has a chance to advise another in regard to matrimony and does not take advantage of it, he is either a hero of self-denial or a very sincere friend. The hospital interne as we know him is thoroughly capable of taking care of himself even in matrimonial matters.

There is a lesson in the matter that is, perhaps, worth the pointing out. It is that the modern young man is apt to be easier "taken" by a woman who knows how to make herself practically useful in life than by one whose whole duty seems only to be as pretty as possible. There is a utilitarian spirit abroad that demands the useful with the beautiful, *utile cum dulce*, and if sometimes an unwary student of Nature turns aside from the dilettante contemplation of butterflies to the serious study of the trim and busy honey-bees, it may be set down as no more than the time-spirit breathing where it will, despite social conventions and the artificial barriers that have ever vainly opposed it. Meantime, no higher or sincerer compliment could be paid to the character of the professional nurse than that doctors who are brought so intimately in contact with her should seek her as a wife. The English-speaking profession may well congratulate itself on the body of self-respecting and respected women which it has raised up for its aid in the treatment of disease, to replace the nondescript nursing material that existed before. Nowhere else as yet have they the trained nurse as we know her here and in England, but other countries are hastening to emulate us in the possession of so good an institution. *Macte virtute puellæ, sic itur ad astra.*

THE English coroner's jury in the Harold Frederic case brought in a verdict of manslaughter against a member of Frederic's household and

against the Christian Scientist who had been in attendance upon him. Some of the details that came out in the evidence during the trial are very pathetic. At first Frederic seems to have consented to have a Christian Scientist attend him. Then, disgusted with the evident sham of it, he asked that her visits be discontinued. Through a member of his household the Christian Scientist continued to gain admittance, until finally Frederic had to appeal to his former medical man to protect him from the annoyance that she was inflicting on him by her visits. Even the appeal of the physician to the "healer" was, it seems, for a time, unavailing. She persisted in calling, at so much a visit of course, the cross examination bringing out very clearly that she was making lots of money by her *Christian* healing art.

The principle of English law under which the verdict is rendered is that the commission or omission of any act tending to shorten the life, even of a person who is mortally ill, is manslaughter. It matters not if such commission or omission be not intended, if there has been neglect of duty, the responsibility for the result remains and must be met. The principle is the one that should be the guide in our own courts. The necessity for legal interference in the matter is made clearer than ever before by the details of the present case.

Mr. Frederic was suffering from heart disease, the result of rheumatism. The importance of rest in such a case, especially as it would seem that emboli had been detached from the heart-valves and thrown into the circulation on several occasions, can scarcely be overestimated. Despite his physician's orders to the contrary, Mr. Frederic had been taken out carriage riding by his Christian healer. Later, when aroused to a sense of the utter inanity of Christian-healing methods, there had been a series of emotional storms produced by efforts to put an end to her persistent calls. All this was calculated to thoroughly depress a system already laboring under a serious failure of compensation and cardiac insufficiency, and undoubtedly Mr. Frederic's life was shortened, probably for years, by these indefensible methods of so-called Chistian science.

If human life is to be at the mercy of some fanatical female member of a household, who thinks Christian Science all powerful against disease, then it is time for the courts to mete out the measure of justice that is merited by such unwarranted assumption of responsibility for human life in serious disease. Common sense can have no weight with people so lost to all sense of reason. It is sincerely to be hoped that the punishment of some of their number, and the feeling of popular execration it will carry with it, will bring the members of this sect to their senses.

THE ETIOLOGY OF HEPATIC CIRRHOSIS.

In the *British Medical Journal* for October 22d, Professor Adami of Montreal adds some notes to the paper on "The Etiology of Hepatic Cirrhosis" which was read for him by Professor Osler at the Edinburgh meeting of the British Medical Association last summer and attracted a great deal of attention. Further study has not confirmed his original view: that there is a specific bacterial cause of hepatic cirrhosis in man, cognate and somewhat similar to the microbe that seemed to be the specific cause of the enzootic affection known as the Picton cattle disease. He had found in the livers of animals which had died from that disease a characteristic polymorphous bacillus, which in the earlier stages of its growth outside the body resembles a diplococcus, in the later stages becomes more bacillary, and when seen in the tissues is present as a diplococcus once more with a faint halo.

A form almost identical with this diplococcus-like body he found constantly present in some twenty human cirrhotic livers, generally within the liver cells. These bodies are extremely minute and can be well studied only with a $\frac{1}{18}$ or $\frac{1}{20}$ oil immersion though they may be recognized with some difficulty with a $\frac{1}{12}$ lens; the method of staining used being carbol-fuchsin and then bleaching in the bright sunlight for several days. It appears on further investigation that these bacillary forms, sometimes assuming diplococcus shapes, were none other than colon bacilli.

This disposes, for the moment at least, of the question of a specific bacterial cause for hepatic cirrhosis though it does not detract from the value of Professor Adami's work. The demonstration that the colon bacillus may assume a diplococcus form in the tissues is extremely interesting. It adds an important link to the chain of facts that bacteriologists have been so long forming and which tend to show

that under the name colon bacillus we have to do with a family type rather than an individual bacterium. It seems pregnant with suggestion, too, as to that crux of bacteriology: Are bacterial types constant, or are they capable of transformation into other types? and looks as though it might throw light upon that other shady question: Have developmental and involution forms of bacteria a specific virulence corresponding to their recognized mature forms?

Meantime, as Professor Adami suggests, it may be that under certain conditions of lowered resistance of liver cells due to alcohol or intestinal toxins the colon bacilli may have specific causative influence in the production of hepatic cirrhosis. Ramond in France has had some measure of success in producing hepatic cirrhosis in animals by alternating doses of bacterial toxins and alcohol. Working along similar lines Adami is now experimenting with alternate doses of alcohol and cultures of the colon bacillus. There is at the end of his paper a hint that he has had some success with this method, though, as he says, he is the more inclined to be cautious inasmuch as his Edinburgh paper, though its conclusions were announced as provisional, "raised some expectations as to the specific nature of ordinary cirrhosis which this present contribution to the study must overthrow." The whole of the investigation has been thoroughly scientific in character, and its results though for the moment misinterpreted, will prove, we feel sure, of great value. The apologetic turn to certain phrases seems scarcely called for seeing the promise the work contains. If all the misinterpretations of appearances in bacteriology were replete with as much prospective gain and present suggestion as this is one might well say, "*felix culpa.*"

ECHOES AND NEWS.

Medical School at Nashville Burned.—The building of the Medical Department of the University of Tennessee at Nashville was destroyed by fire November 11th. No definite information has yet been received regarding the loss or the future arragements.

Bubonic Plague in Vienna.—A cablegram from the U. S. Consul at Vienna, dated November 2d, announces that plague infection to emigrants coming to America is improbable. There have been in all six cases of plague in Vienna, all hospital attendants, with three deaths.

Another Medical Mayor in Cuba.—General Wood has appointed Dr. Vincent Gomez of Brooklyn, Mayor of the city of Gibara. Dr. Gomez was formerly Instructor in Otology at the New York Polyclinic, Assistant-surgeon at the New York Eye and Ear Infirmary, and a Captain and Assistant-surgeon in the 112th Regiment, National Guard, New York.

Health of the Troops at Manila. — The weekly report of the sickness among the American troops gives 1894 as the number of sick. There are among these 137 cases of typhoid and 637 cases of malarial fever; there are 7 wounded and otherwise injured men. The deaths were: Typhoid fever, 4; dysentery, 2; abscess, 1; meningitis, 1; pemphigus, 1; drowning, 1, and smallpox, 2.

Proposed National Cemetery at Santiago.—The War Department is considering the establishment of a national cemetery near the city of Santiago, Cuba, where the American soldiers who died fighting before that city can be interred. It is altogether probable that a site for a national burying-ground will be laid off soon after the occupation of the island by the American forces.

Mortality in the Recent War with Spain.—The official statistics, compiled under the direction of the Commissioner of Pensions, show that the total number of deaths on the American side due to the war was 2906 up to October 1st. As only 348 men were killed in battle or died from their wounds, the horrible death-rate from sickness becomes apparent, giving us a mortality from disease of 2558.

The New York Medical League.—A meeting of the New York Medical League was held at the Academy of Medicine, November 18th, at 8:30 P. M. The subject for consideration was "Illegal Practitioners of Medicine and Surgery." The subject was discussed by Mr. Robert C. Taylor, Dr. George Tucker Harrison, Dr. Wickes Washburn, Dr. Thomas H. Manley, Senator Pavey, Mr. W. A. Purrington, and others.

Leprosy in Brazil.—The U. S. Marine Hospital Service Sanitary Inspector at Rio Janeiro states that an estimate of three thousand lepers at present in Brazil cannot be considered an exaggeration. During the past year nineteen lepers have died there. Death was caused in eight cases by cachexia, in one case by the consequences of lepra anesthesica, in four by tuberculosis, and in six by intercurrent diseases.

Cure for Military Nostalgia. — Dr. Harrison, a colored physician of Wichita, Kans., has received from a member of one of the colored regiments in Cuba a letter stating that many of his comrades have forgotten home and former heart ties sufficiently to fall in love with and marry Cuban and half-breed Spanish girls. This letter has caused consternation among the colored women of Wichita who had husbands or sweethearts among these troops.

Postponement of the Third Pan-American Medical Congress.—In accordance with the request of the Government of Venezuela and of the Committee on Organization,

the third Pan-American Medical Congress, appointed to meet at Caracas, Venezuela, December, 1899, has been postponed to December, 1900. This action has been necessitated by the local rebellion, which has only recently been suppressed, and by a serious scourge of smallpox which has quite upset not only the minds of the physicians of that country, but also the entire people.

The Alvarenga Prize Essay.—The Alvarenga prize of the College of Physicians, Philadelphia, for 1898 has been awarded to Dr. S. A. Knopf of New York City for his essay, entitled "Modern Prophylaxis of Pulmonary Tuberculosis and Its Treatment in Special Institutions and at Home." The next award of the Alvarenga prize, amounting to about $180, will be made on July 14, 1899, provided an essay deemed by the Committee of Award worthy of the prize shall have been offered. The particulars can be obtained by addressing Thomas R. Neilson, Secretary, College of Physicians of Philadelphia.

Yellow Fever at Havana.—Yellow fever continues its deadly work among the Government officials who have been sent by our Government to attend to the preliminaries attendant upon the garrisoning of Cuba. Lieut.-Colonel Charles W. Williams, Chief Quartermaster at Havana, was smitten with the disease November 4th, and died November 11th. Orderly Stuart, who was acting as clerk in the Quartermaster's Office, and who was attacked by yellow fever a few days earlier than Colonel Williams, also died November 11th. Captain Colbert, aide to Colonel Williams, is now suffering from the same disease.

Beatty vs. Cullingworth Once More.—Miss Beatty, the English nurse, who was beaten in her appeal to a higher court in the matter of the oophorectomy that she claimed was done by Dr. Cullingworth without her authorization, having failed to secure any modification of the verdict on further appeal to the Home Secretary, now threatens to take the law into her own hands. It would seem, at least in this case, that oophorectomy does not always "minister to a mind diseased" in the way it is sometimes claimed to. From the utterance of such threats to the execution of them is but a step that has been too often taken in latter-day experience to allow them to pass unnoticed, and careful surveillance for a time would seem to be called for in this case.

Colonel Waring's Report on Havana.—The *Army and Navy Journal* of November 12th gives some of the sanitary calculations which the late Colonel Waring is said to have made for Havana. He found that city to be "the worst case of filth and carelessness in a city that he had ever known of in his long experience with these matters. In addition to a sewage system, of which not the slightest trace exists in Havana, and new pavements for the streets, the Colonel thought that 100,000 water-closets ought to be imported, and each house provided with one. Perhaps the whole cost would amount to nearly $20,000,000, but it is a sacrifice that must be made in the interests of the United States and of humanity. Not only will yellow fever disappear, but many other infectious diseases which are annihilating the Cuban people. The work is necessary not only at Havana, but at every port from which direct communication is had with this country."

Medical Advertising in India.—Some of our East India medical brethren who went to England to study medicine seem to have learned more than pure science in their contact with the profession in England, as the following advertisement will show. The *Indian Medical Record* copies it from a local paper as a sample of what Western medical culture has done for an East Indian: "Dr. S. M. Varis, M.B.C.M., Edin., Consulting Physician and Surgeon. Consultation all hours. Free 9 to 11 A. M. Notice: Dr. Sayad Mahomed Varis, Surgeon! Good news to thee, O heart, a Jesus-like man has come. Be it known to the seekers after bodily health, and to those in the clutches of deadly diseases that the Aristotle of the times and the Galen of the universe, Dr. S. M. Varis, M.B.C.M., after learning the art of medicine and practising it in Great Britain, has come to this town of Lucknow. He studied for six or seven years in modern Athens, *viz.*, Edinburgh, which is the capital of Scotland, and he obtained the diploma of a physician and surgeon, and there for three years he established himself in practice and performed Christ-like miracles. It is our good fortune that he has established himself here. It is hoped that whosoever will apply to him for treatment will fill his pockets with pearls of health (*sic*). He lives close to Kaisar Bag, near Share Darvoza, opposite the telegraph office, in house No. 1. Patients can consult him all day." It is not said that the patients who apply are filling the pockets of Sayad Mahomed Varis, M.B.C.M., Edin., with the pearls of wealth, but as the native Indian population are not less gullible than their cultured Western fellow men, it is to be supposed that he is reaping a precious harvest.

SPECIAL ARTICLE.

NEW BUILDING OF THE MEDICAL SOCIETY OF THE COUNTY OF KINGS, BROOKLYN.

LAYING OF THE CORNER-STONE.

A MOST important occasion for the medical profession of the Borough of Brooklyn was celebrated on the afternoon of the 10th inst., in the laying of the corner-stone of the proposed new home for the Medical Society of the County of Kings. A rain-storm prevailing, the literary exercises arranged for the occasion were held in the drill-room of the Twenty-third Regiment Armory on Bedford avenue. The plot of ground owned by the Society is on the easterly side of Bedford avenue, south of Atlantic avenue—a very central point—the cost of which was not far from $18,000.

The duty of laying the corner-stone devolved on the President, Dr. Joseph H. Hunt, who, with a few of his fellow officers, stood in the rain while making a brief address. The receiver of the corner-stone was filled with a metallic box containing numerous papers and photographs commemorative of the first half-century of the

Society. The chairman of the meeting was Dr. Frank E. West, by whom the Reverend Dr. R. S. Storrs was introduced, who offered the prayer invoking the Divine blessing upon the new enterprise. Dr. George McNaughton, ex-president of the Society, and generally accredited as the father of the building scheme, delivered a historical address showing the progress of the organization since its formation in 1822. He was followed by the Hon. Seth Low, LL.D., President of Columbia University, who dwelt upon the opportunities for good, implied in the library and educational powers of a great and faithful medical association. Mr. Low adverted to the fact that the strides of medicine, during recent years, are not within the scope of the knowledge of the general public. "Those persons who have not looked into medical affairs know but little about the progress made in that profession in the last twenty years. The student sees the wonderful progress that has been made, and I hazard nothing in saying that the progress of medicine and surgery is equal to, if not greater than, the progress made in other lines. For instance, the largest department in Columbia College today is that of bacteriology, which was unknown to educational bodies twenty years ago. As the years go by, physicians will learn to make mankind immune to more and more of the dangerous diseases now so much feared. The active practitioner of to-day must be a student as well as a practitioner, therefore, the medical profession needs such a building as your Society is about to erect. The idea of its being the mere home of a club, as has been stated in one of our higher courts, is preposterous. It is to be a place for study and learning. The science of medicine is a living thing, a growing thing. Consequently, those actively engaged in it must read all the new books appertaining to the subject, and so this new building and library are needed. A technical library is light giving. It is the headlight of a train of study and leads the way. A great library of medicine is a great storehouse of knowledge for the protectors of the community to gather strength and wisdom from to fight off disease. There is no profession more brave and more constant in its devotion than that of the doctor. Many Brooklyn doctors sacrificed their lives in the fight against cholera years ago. You have been told that your Society owes its birth to a similar fight against disease. Therefore, the community owes to you help which it should not be tardy in giving. Your library should be contributed toward as a great public work."

New Building, Medical Society of the County of Kings.

When completed the new structures will be one of the many beautiful buildings in the vicinity. It will be three stories in height, 95x85 feet in size. The architec-

ture will be colonial, of gray brick, with stone trimmings. On the first floor will be located an office, reception-parlor, ladies' room, cloak-room, and an auditorium with a seating capacity of four hundred. The reading room will be on the second floor, while the library, with room for 100,000 volumes will adjoin it. The construction will be fireproof, and by giving special protection to its library, it will at once begin its work of accretion by attracting to it the medico-literary treasures of its adjacent territory. "Growth in safety" will be its watchword from this time onward. The institution has a homelike and inviting prospect, and will be all the more used and appreciated by the local profession for the reason that its growth and assured success are to be attributed almost solely to the hard work and liberal spirit of its own membership. It is not too much to expect that contributions, gifts, and bequests will mark each future year of its history. The building committee reports that in about four months a considerable portion of the rising structure will be ready for occupancy.

CORRESPONDENCE.

IN REGARD TO YELLOW FEVER AT HATTIESBURG, MISS.; A CRITICISM OF REV. MR. PEEBLES.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In your issue of the 29th ult., I note an article signed "I. L. Peebles, M.D.," from Hattiesburg, anent the yellow fever that has prevailed in our Southern country for the past sixty or eighty days.

In the first place, I will say that I have known the gentleman referred to some years, and while I considered him an exemplary man and an excellent preacher (Methodist), I never yet heard of his having studied medicine, to say nothing of his claim to be an "M.D." There is also another letter from the same prolific source making a scurrilous attack upon the Board of Health in the *New Orleans Advocate*.

I will pass over his unkind remarks, and in justice to the honorable and capable men who compose the board, quote a few plain facts for the consideration of your readers.

In the first instance, I will emphatically aver that we have yellow fever, and even nurses who have grown old in the work so recognize it. Secondly, our city got her fever directly from New Orleans, just as Hattiesburg, and our death-rate is about the same as in 1871, our last epidemic. Thirdly, failure of the Louisiana Board to acknowledge the presence of the fever, and its persistent denial of it is the prime reason why all this country was infected. Had the board dealt with us fairly we could easily have kept out the fever by excluding the people from infected points. But from the letter of your correspondent I judge that he has aligned himself with the "business interests," and counts human life as but dross in the presence of a 16-to-1 silver dollar. A true man or physician deems it almost a crime to conceal or deny an infectious disease, and thereby endanger the life of another.

As for panics or wild running from infected localities: Just 113 people left here for the North, and about 60 or 70 went out in the country.

The death-rate here will be six or seven per cent., but we prefer not to have it at all, as every death from a preventable disease is a tragedy.

When the fever was first found in the third ward of Natchez it was completely stamped out, and no new cases have appeared in that neighborhood. Had we then been able to trace the source of infection, as we did later, several valuable lives might have been saved. We found a regular nest in the north end of the first ward, near the city hospital, from which we traced the fever in the third ward. To date we have had 60 cases, located as follows: First ward, 52 cases (original point infected); second ward, 3 cases; third ward, 4 cases, and fourth ward, 1 case. These figures are significant. They prove that the disease is amenable to scientific treatment, and can be handled, and a general epidemic prevented. Our city is densely populated, and the oldest in the State. We have a population (city census of 1898) of 12,998, practically 13,000, which gives us less than 1 to every 200 people affected with fever, and very few immunes here owing to our freedom from fever since 1871. With exceptional weather for its development, with doctors in control of the Health Board, we had sixty cases of fever. Twenty-seven years ago, with the town full of immunes made during the epidemics preceding, and the town only two-thirds the present size, we had 1200 cases and 119 deaths. (Figures are official.)

We reported the fever, closed up churches, and urged people to stay at home. They complied, and we saved the town from an epidemic.

What a contrast 1871 presents to 1898, when (now) "experts" are so foolish as to report infectious diseases and thus injure the "business interests" of a town and community!

J. C. BALLARD, M.D.,
Chief Health Officer.

NATCHEZ, Miss., November 9, 1898.

[It is barely possible that the Rev. Mr. Peebles did not wittingly assume, in his letter to the MEDICAL NEWS, the title of Doctor of Medicine, but that the initials were appended to his name by an overzealous compositor without our discovering the error. If so, we tender him an apology. It gives us pleasure to publish the above letter from Dr. Ballard, as it clearly sets forth the character of the infection at Hattiesburg, and, at the same time, stamps with disapproval the public expression of a layman who has wandered far afield from his proper vocation.—ED.]

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

AN UNPOPULAR MEDICAL COLLEGE—A QUICK METHOD OF GRADUATION—HOT AIR IN JOINT DISEASES—HERNIA—DIPHTHERIA ANTITOXIN—AN ISOLATING WARD FOR THE GERMANTOWN HOSPITAL—PERSONAL NOTES—HEALTH-BOARD STATISTICS.

PHILADELPHIA, November 14, 1898.

FROM present indications it appears probable that the storm brewing in medical circles here may break forth at

any moment. There is an institution in Philadelphia whose methods do not always find favor with the majority of the profession, and an article by a contemporary last week has only served to add fuel to the fire, by threatening to make public its methods of stealing students from rival institutions. In a NEWS letter of some four months' ago a Baltimore medical college was accused of accepting and graduating students who had failed to graduate in Philadelphia earlier in the same year, making attendance at the Baltimore institution a matter of about ten weeks, although its announcements call for terms of six months, the last to be passed within its own walls. Through a typographical error "*The* Baltimore Medical College" (a reputable college) was substituted for "*a* Baltimore medical college" which called forth a righteous and indignant protest from the former and in consequence a statement from the NEWS as to the manner in which the error occurred. In order to be perfectly secure in his premises the writer allowed the matter to remain where it was until a catalogue of the guilty institution containing the names of the students in question could be obtained and now respectfully calls attention to this transaction again, placing the responsibility where it rightfully belongs, surely a more serious offence having been committed than that which our local institution has been accused of. Under the State law these men have the right to be examined for a license to practise medicine and yet they obtain this right unlawfully, and one barrier between the ignorant medical graduate and the community is broken down.

We should like to call the attention of our zealous Philadelphia contemporary and of the Association of American Medical Colleges to this flagrant breach of trust, the college claiming to be a member of the latter.

At the Philadelphia Academy of Surgery last week Dr. H. Augustus Wilson presented a paper on "Hot Air in Joint Diseases," the paper being practically a summary of the results achieved by its use for two years in various affections. Dr. Wilson found it useful in sprains, in softening bands in ankylosed joints, in aiding absorption in cases of hydrarthrosis, and while further use only can determine the question, it seems to be useful in tubercular-joint disease. In rheumatic affections and in chronic rheumatoid arthritis he believes it increases pain and has proved to be very disappointing. Among three cases of hernia reported by Dr. J. Chalmers Da Costa was one occurring in a man aged forty-one, who presented symptoms of strangulation in an enormous scrotal hernia, which extended down to the knees, pain, nausea, complete constipation and tenderness on pressure being present. The condition had existed from boyhood, gradually increasing until lately when the increase became very rapid. The mass, which was irreducible, was found on incision to include the cecum, the appendix, the ascending, and a portion of the transverse, colon, a large part of the ileum, and a portion of the omentum. Restoration was made to the abdominal cavity after removal of the omentum and Bassini's operation carried out as far as possible. Recovery followed, a slight relapse being relieved by a truss.

Another interesting paper of this week was a "Report of Five Cases of Diphtheria" read by Dr. John M. Swan before the Philadelphia County Medical Society. It was interesting because of the absence of any false membrane in the throats of the patients, and because of the good results achieved by the use of antitoxin. The cases occurred in one family, the mother and the several children being affected; typical symptoms were present and though the false membrane was absent, inoculations from the affected throats revealed the presence of the Klebs-Loeffler bacillus. Inoculations of from 250 to 500 units of antitoxin were given, causing a return within twenty-four hours to the normal temperature with no unfavorable results. A solution of nitrate of silver, one dram to the ounce, was then applied locally which rapidly caused disappearance of the bacilli, a method advocated by Dr. Aldred Hand, Jr., in a paper read some time ago; in no case was it necessary to make more than two applications.

The Germantown Hospital is to have a new isolating ward through the generosity of Stephen Green as a memorial to a member of his family. It is to be built of brick and tile, consists of one story and basement and will contain three rooms for patients, one for nurses, a diet-kitchen, toilet-room, and a large reception-hall.

Dr. Joseph Neff, Director of Jefferson Hospital and William Potter, President of the Board of Trustees, are candidates for the office of President of the Union League Club.

Dr. William P. Read, Assistant Demonstrator of Pathology at Jefferson, has resigned to enter the United States service, and Dr. Charles Frazier has been appointed Visiting Surgeon on the staff of the Philadelphia Hospital in place of Dr. J. William White, resigned.

The total number of deaths occurring in Philadelphia as reported at the Health Office for the week ending November 12th was 397, of which 102 occurred in children under five years of age. The number of new cases of contagious diseases was 254 reported as follows: Diphtheria, 112 cases with 24 deaths; scarlet fever, 27 cases with 1 death; typhoid fever, 115 cases with 5 deaths.

MEDICAL MATTERS IN CHICAGO.

[From a Special Correspondent.]

PROTEOLYTIC VALUE OF MALT EXTRACTS—CONGENITAL APHASIA OF FAMILY TYPE—SCROFULOUS OPHTHALMIA—MULE'S OPERATION—CONGENITAL DISTICHIASIS—SARCOMA OF THE LID—EXTENSIVE FISTULA IN ANO—FLOATING KIDNEY, TUBAL PREGNANCY AND GALL-STONES IN ONE PATIENT—TREATMENT OF ULCER OF THE STOMACH.

CHICAGO, November 14, 1898.

AT a meeting of the Chicago Medical Society, held October 26th, Dr. Charles H. Miller presented the subject of "The Proteolytic Value of Malt Extracts." After briefly reviewing standard authorities and giving the results of experimentation, he drew the following deductions: (1) Properly prepared, light-colored, semi-liquid extracts of malt, possessing strong amylolytic power, have also positive proteolytic value, though decidedly

less marked than the better known ferments, pepsin and trypsin. (2) The reaction of the media bears an important relation to the results obtained. This influence is believed to be as follows in sequence of greater activity: 2 per cent. lactic acid, .5 per cent. sodium carbonate, .6 per cent. sodium chlorid (neutral), and .2 per cent. hydrochloric acid. (3) Judging from experiments, and in the proportions employed, the proteolytic power of malt extracts is about 5 per cent. of that of pepsin or pancreatin. (4) The dry diastase preparations were not found to possess proteolytic power. The best results were obtained by a freshly prepared extract of malt just before use. Good malt extract is a valuable food, concentrated and immediately assimilable. It is capable of immediately converting enormous quantities of non-diffusible carbohydrate food-starches into soluble dextrin, or maltose forms, ready for the use of the body. It is, in the amounts commonly administered, capable of largely converting the proteids of an ordinary meal into diffusible peptones. Malt extract is a first-class remedy, and the simplest rules of combination render it doubly satisfactory to use. Regarding administration, it should be given just before or with the meal, and can always be advantageously combined with lactic acid to pleasant tartness, other medicines not interfering.

Dr. Harold N. Moyer read a paper on "Dumbness or Congenital Aphasia of a Family Type without Deafness or Obvious Mental Defect." He described the case of a boy, nine years of age, otherwise bright and healthy, who understood all that was said to him, but who had spoken only one word, "Mama," until his eighth year. It could not be learned at what time of life the boy acquired this word. Inquiry into the family history showed that the father was totally aphasic until six years of age, and that two brothers and one sister were similarly affected, none of the latter speaking until four years of age. A paternal uncle and cousins were affected with lallation all their lives. The two brothers of the patient grew up and occupied positions in life above that of the parents. The father and two grown sons had an excellent command of language, free from all defects of articulation. The essayist referred to several classical examples of sudden speech in those who had been previously dumb; the son of Crœsus, and the Samian athlete. The extreme rarity of the affection was shown, an examination of 4485 mutes showing this condition in only 7, and many of these were more defective as to general mentality than those which he described. The explanation of Bastian was referred to in which he claims that language is to a certain extent instinctive, and in these cases there is some barrier to the emission of speech; under the influence of strong emotion this is swept aside and speech follows. One of the patients coming under observation did not speak until the fourth year, then it suddenly began, at first imperfectly, but in three months he spoke as well as the average child of his age.

Dr. Henry Gradle discussed to subject of "Phlyctenular or Scrofulous Ophthalmia." After referring to the frequency of this affection and its preponderance in girls, he described it as a disease of childhood, seen rarely after puberty, and then only in patients who had been subject to it since early childhood. The characteristic lesion is the phlyctenule, not a vesicle, but a translucent papule (of leucocytes), which in typical cases disappears by absorption in five to eight days. The serious aspect of the disease is the liability to relapses, often in multiple form, the frequent delays in the disappearance of the phlyctenules, and particularly their transformation into larger papules, into corneal infiltrates, which often ulcerate, or into diffuse patches of superficial keratitis with new formation of blood-vessels. All these manifestations are but metamorphoses or sequelæ of phlyctenules. Coming to the treatment he endorses the hygienic measures generally adopted in tuberculosis, namely, an outdoor life, proper feeding, baths, and, if indicated, cod-liver oil. These measures seem to protect fairly well against relapses, but their influence requires too long a time to be of immediate benefit as far as the attack at the time is concerned. In the local treatment he recognizes the influence of calomel dusted into the eye, especially when used two to three times daily. Atropin is of decided influence when there is pronounced ciliary irritability, and especially when the pupil is narrowed or resists the dilating influence of the drug. But whenever the process is not accompanied by much irritation, or when the pupil yields at once, atropin seems to exert no influence of any kind.

At the October meeting of the Chicago Ophthalmological and Otological Society, Dr. W. F. Coleman exhibited a patient upon whom he had performed Mule's operation some two weeks before, and who had been wearing the artificial eye for two days. The operation was followed by very little reaction, which he ascribed to cauterizing the inner wall of the sclera with 95 per cent. carbolic acid and the free use of hot water. Dr. F. C. Hotz said that practically the only advantage from Mule's operation is that the sulcus in the upper lid under the brow is less deep than in the ordinary enucleation. Dr. Casey A. Wood has performed Mule's operation twice, and said there is very little in the procedure to recommend it over a proper enucleation or evisceration.

Dr. Wood presented two cases, father and daughter, of congenital distichiasis. The hairs were extracted by the use of nitric acid inserted into the base of the lesion by means of a fine tooth-pick. Dr. Hotz reported a case of unusual tolerance to mydriatics. Dr. Wood finds that there is a dermal idiosyncrasy in many patients after the use of atropin.

Dr. C. P. Pinckard detailed a case in which a single drop of atropin produced marked constitutional symptoms, but not any skin symptoms. He also detailed a case of sarcoma of the lid, and dwelt upon the differential diagnosis between sarcoma and chalazion, saying it is difficult before a section of the tumor is made and examined.

At the November 2d meeting of the Chicago Medical Society, Dr. J. R. Pennington reported a case of extensive fistula in ano in which there was only one external opening. In operating in these cases it is important to recognize their conformation, particularly when there is one or more external openings on each side of the anus;

otherwise the operator is apt to proceed as though he has two separate and distinct fistulæ to deal with, and by following the advice given in some text-books, slit up first one sinus, then the other, and, when too late to remedy the mistake, recognize that he has divided the sphincter in two or more places, following which the patient has incontinence of feces and a remaining fistula. In operating on this patient he did not divide the sphincter, and consequently there was no incontinence of feces. Patient made a good recovery. He also detailed a case of incontinence of feces following an operation for simple fistula.

Dr. Alexander Hugh Ferguson reported the case of a woman, thirty years of age, upon whom he had operated for floating kidney, tubal pregnancy, and gall-stones. The patient was treated surgically on two different occasions for these conditions. He exhibited both the patient and the specimens. Dr. Arthur D. Bevan narrated a case in which a diagnosis of gall-stones, floating kidney, and appendicitis was made; an operation was performed, and the diagnosis verified.

At a meeting of the Chicago Medical Society, held November 9th, Dr. James B. Herrick contributed a paper on "The Treatment of Ulcer of the Stomach by Rest in Bed and Rectal Feeding." He said that physicians often oppose the treatment or give it but a half-hearted approval. By rest in bed and rectal feeding the natural tendency of the ulcer toward recovery is encouraged by the removal of all mechanical and chemical irritation. Several objections have been made to rectal feeding. The objection that the rectum will not submit to repeated enemata, but will give out, is answered by the fact that when suitable enemata are properly administered, the rectum will tolerate this method of treatment for many days or many weeks. In carrying out the treatment it is important to secure the consent of the patient by a clear explanation of the reasons for the treatment, the probable length of time required, etc. The bowels should be emptied by a preliminary laxative and cleansing enema. Absolute rest in bed should be required for from two to six weeks. Nothing should be given by the mouth, not even water, for from three days to three weeks. Nourishing enemata should be given at regular intervals, say of four hours, by means of a soft rubber tube inserted high into the rectum. Enemata can be given once in twenty-four hours, a period of eight hours rest, as, for example, from midnight to eight in the morning, being desirable. The quantity and kind of food, as well as the hours, can be varied in individual cases. A simple enema of water is to be given every morning. This may be retained, in which case it quenches thirst; it may be rejected, acting as a cleansing enema. As pain, tenderness, and vomiting cease, the enemata can be gradually withdrawn, and peptonized milk or other light diet carefully substituted by the mouth. The patient should be allowed to get out of bed only after rectal alimentation has been entirely stopped. It is best to keep the patient in bed for at least four weeks. Iron may be necessary for the chlorosis so commonly present. This should only be given when a light diet is tolerated. The results are almost an immediate lessening of pain, vomiting, and nausea. There may be emaciation and weakness, which will disappear quickly when stomach feeding is resumed. A cure is the result in the larger number of recent cases. This rational method of treatment, allowing Nature to work the cure, deserves the warmer indorsement of text-books and physicians, particularly as medicinal treatment is so unsatisfactory. It should be employed in every case, either mild or severe.

OUR LONDON LETTER.

[From Our Special Correspondent.]

DEATH-PENALTY FOR PRODUCING ABORTION — A CLEVER BLACKMAILING SCHEME — SLAUGHTER-HOUSE INSPECTION—THE LONDON POST-GRADUATE SCHOOL—A SPECIAL COMMISSION TO INVESTIGATE THE PLAGUE—LONDON MEDICAL SOCIETIES.

LONDON, November 10, 1898.

THEY have a way of enforcing laws to the very letter in England which is somewhat startling to the Western mind. In the recently decided Whitmarsh case which has been attracting the attention of the profession on both sides of the Atlantic, the accused was actually found guilty of wilful murder and condemned to death, for operating to produce an abortion, which operation ultimately resulted in the patient's death. The sentence was chiefly due to the judge's charge which instructed the jury that if they believed the defendant knew the operation to be felonious and was aware that it was attended with danger to the woman's life, they must find him guilty of murder. This, of course, rests upon the old legal maxim that all the consequences of a wilful felonious act must be construed as wilful, and if loss of life result, then the offender is guilty of "constructive murder."

It is beginning to be doubted even in legal circles whether this reverend maxim is really good law and sound justice, but the knowledge of the mere possibility of its application in our American courts would have an electrical, purifying effect upon the atmosphere of abortionist circles. It is good law in cases of this class, if anywhere on the foot-stool.

Altogether the abortionist has been having an uneasy time of it here of late, for the "other side of the house" has not yet recovered from the excitement into which it was thrown a few weeks ago by the Mitchell blackmailing letters, the details of which are familiar through the popular press. The plan was fiendishly ingenious, the only wonder being that it should have been reserved for a slow and stolid Briton to evolve the brilliant idea of securing a list of the purchasers of a certain "Female Regulator" advertised in the religious journals, and serving them all with an "official" letter, announcing that legal proceedings had been commenced against them for the "fearful crime" of attempted abortion, which could only be stopped by the prompt remittance of $10 "to cover costs" and a "solemn oath before God" never to repeat the offense.

It ought to make our native sharks blush for their stupidity. The best thing about the rascally affair is that its originator found it necessary to flee so soon that he could not have reaped much profit from his scheme, though its admirable working is shown by the more than 600 letters with enclosure—and oath—intercepted by the po-

lice, while the purchasers of the "regulator" have had a sharp but salutary lesson.

The London County Council is struggling with the question of slaughter-house inspection. The hybrid system of a public abattoir, plus numerous private slaughter-houses, prevailing in many of our American cities, is in force here. This has proved, as everywhere else, unsatisfactory, and a proposal to abolish private slaughter-houses is before the Council, meeting of course with warm resistance from the butchers. The supporters of abolition are turning an interested eye across the Atlantic to gather the results of the mixed system in our large cities. If they are guided by what they see there the reform will not be long delayed.

It will be welcome news to our students that the new London Post-Graduate School is making rapid progress with the fitting up of its new building in Gower street and hopes to be in operation by January. In addition to its own clinics and lectures it will have a resident secretary who will keep a list of the dates, hours, and subjects of the clinics and clinical lectures at all the principal hospitals in London, so that it hopes to form an information bureau of things medical for the benefit of physicians visiting the city.

Galvanized at last into activity by the continued smouldering of the plague in Bombay and neighboring towns, the English Government has appointed a special commission to visit India and thoroughly investigate the whole question of the disease, with special reference to preventive inoculation. Tardy as the action is an admirable choice of personnel has been made in placing at the head of the commission Professor Fraser of Edinburgh, so well known for his brilliant work upon the toxins of snake venom. His associates, Dr. Rieffer of the Egyptian Sanitary Service, and Dr. Wright of the Army Medical School at Netley, are worthy of their chief. "It's an ill wind" etc., for it is creditably reported that the tragedy of science at Vienna was the last straw which tipped the delicately balanced and hesitating official scales in the direction of action.

The Medical Societies of London have just fairly begun their season's work. It is a great pity for the sake of both visitors and residents that there is not more concentration and unification among them both as to places of meeting and ground covered. Disregarding the local and suburban organizations, the great central societies of London have their places of meeting scattered all over an area some three miles square in the heart of the city. The overlapping in ground covered is even more unfortunate for there are no less than five general medical societies corresponding to the Section on Medicine of our New York Academy, leaving out of count the numerous specialist organizations.

At the Pathological Society Mr. George Shattock, Pathologist to the Museum of the Royal College of Surgeons, presented a most interesting acromegalic skull, discovered by him among the normal crania in the collection of the college. The skull had been purchased with a number of others in Rome but nothing further was known of its history. It was obviously acromegalic, presenting the overgrown jaw, the thickened calvarium, and the large pituitary fossa. The cranial bones were not only thickened but greatly increased in density so that the skull was enormously heavy, while in many cases of acromegaly the enlarged bones are so porous as to even weigh less than the normal. Dr. Shattock also alluded to the skull and skeleton of John Hunter's Irish giant in the museum, which both he and Dr. Cunningham regard as clearly acromegalic. One after another the giants are falling into the acromegalic line, until now one can almost double Sternberg's estimate of five years ago, that forty per cent. of all giants are acromegalic. It would almost seem as if the chief difference between giantism and acromegaly lay in the time of commencement of the disease; if before puberty, giantism results; if after, acromegaly. The reference to the Irish giant recalls a curious little bit of the history of the acquisition, which illustrates the dogged persistence of the great surgeon. He was acquainted with Byrne for a number of years before his death and had several times offered him a large sum for the possession of his body after death. The poor giant, not unnaturally, took such a dislike to the idea that on his death-bed he paid a fisherman heavily to promise to carry his body three miles out to sea and weight it heavily and launch it overboard. But Hunter was not to be baffled; he "saw" the fisherman, told him to carry out his instructions to the letter, with the trifling addition of permitting him to accompany him in another boat and attach a line to the body before it was cast overboard.

TRANSACTIONS OF FOREIGN SOCIETIES.

France.

ANEURISMS CURED BY SUBCUTANEOUS INJECTION OF SOLUTIONS OF GELATIN—SIGNS OF THE BEGINNING OF PULMONARY TUBERCULOSIS—RESECTION OF LARGE INTESTINES—ACTINOMYCOSIS OF THE UMBILICUS—RESECTION OF NERVES FOR TRIGEMINAL NEURALGIA—REMOVAL OF FOREIGN BODIES FROM THE FEMALE BLADDER—DIAGNOSIS OF INTESTINAL LESIONS AFTER CONTUSIONS—AMPUTATION OF THE WHOLE UPPER EXTREMITY FOR CANCER—TUBERCULAR PERFORATION OF THE HARD PALATE—SECOND CONGRESS OF GYNECOLOGY, OBSTETRICS, AND PEDIATRICS.

AT the Academy of Medicine, October 11th, LANCEREAUX detailed "Three Cases of Aneurism Which Had Been Cured by the Subcutaneous Injection of a Two-per-cent. Solution of Gelatin in Normal Salt Solution." Two of these patients had aneurisms of the aorta, and the other an aneurism of the right subclavian. From 6 to 8 ounces of the solution was injected and the dose was repeated as often as was necessary to accomplish the coagulation of blood in the sac. These injections, which have an incontestable value in aneurisms of a sacculated form, are of no use in fusiform aneurisms, for there cannot be a sufficient slowing of the blood-current in such a dilatation to permit of a cure by clotting.

HUCHARD succeeded in curing an aortic aneurism by fifteen injections of the gelatinous fluid. He has also stopped hemoptysis in phthisis by the same means. He looks upon the treatment as a most painful one and not

altogether free from danger, especially if there is a branch artery given off in the immediate neighborhood of the aneurism.

Two fatal instances of the employment of gelatin occurred in the practice of Boinet and Barth. In one patient the injections resulted in the narrowing of the pulmonary artery, another was followed in a short time by the development of a bilateral pulmonary tuberculosis; while the other patient went into collapse and died almost immediately after receiving an injection. These instances confirm the power of gelatin to increase the coagulability of blood, but they also show that great caution should be observed in its administration. In no case ought the solution to exceed one per cent. and the injections should be made at sufficiently long intervals to enable the physician to judge of the effect of one before another is given. The patient should remain in bed throughout the period of treatment.

FOURNIER mentioned a possible cause of error in the diagnosis of aortic aneurisms. He once made the diagnosis of this condition in a syphilitic subject, but three weeks after antisyphilitic treatment had been begun all sign of the aneurism had disappeared. The condition was not one of aneurism but, as he has since had opportunity to demonstrate several times at autopsy, there was a gummatous infiltration in front of the aorta which simulated an aneurism.

FERNET said that there are certain signs of commencing pulmonary tuberculosis which are sufficiently reliable to deserve mention with those which have become classical. They are those due to an enlargement of the tracheobronchial glands, and to the congestion of the base of the affected lung. The enlargement of the glands is well brought out by percussion upon a pleximeter, combined with auscultation. These glandular conditions follow the changes at the apex of the lung so promptly that they are of great value in the diagnosis of early phthisis.

At the session of October 18th, BOECKEL spoke of "Three Resections of the Large Intestine" which he had done. One was for carcinoma of the descending colon. The ends were sutured and the patient recovered. A second was for tuberculosis of the cecum. Here anastomosis was made between the small intestine and the ascending colon after removal of the cecum. This patient also recovered. The third was for carcinoma of the cecum and the same operation was done as for the tuberculosis of the cecum. The patient died, however, on the sixth day. The autopsy showed that the operation, even if successful, would have been of little benefit, as there were great secondary nodules in the liver, peritoneum, and retroperitoneal glands.

REBOUL removed a spongy tumor from the umbilical region of a man, aged twenty-one years, who had been working in the harvest-field. The wound healed primarily. Section of the tumor showed it to contain the grains of actinomycosis, and in several places there were areas of suppuration, in the center of which were fragments of the beard of wheat, surrounded by the characteristic grains of the disease. The diagnosis was confirmed by cultures made on potato.

At the Surgical Society, October 5th, GUINARD said that he had resected the Gasserian ganglion once, for facial neuralgia, following the method of operation recommended by Poirier, and obtained complete relief from the attacks of neuralgia. He had twice before operated on the same patient, once resecting the alveolar margin with only transient relief; and followed this opertion by that of resection of the superior maxillary nerve and Meckel's ganglion. There was no relief whatever obtained by the latter operation. In seven other patients he had resected the superior maxillary nerve and Meckel's ganglion by Segond's method.

The results obtained upon six of these patients were perfect, and there was no return of the neuralgic attacks. The time since operation varied from six months to three years.

POIRIER admitted that the removal of the Gasserian ganglion is feasible, but added that it is a dangerous procedure. He performed the operation upon a man aged sixty-three with a fatal result. The operation itself was without complication, except an annoying flow of cerebrospinal fluid from a small tear in the dura mater, and there was little hemorrhage. The ganglion was removed without difficulty and the dressing applied. Scarcely had this been accomplished when the patient died.

POTHERAT insisted upon the necessity of having the hook directed properly in the attempt to draw out the Meckel ganglion. This direction is from before backward. Otherwise one is likely to miss the nerve and to penetrate the orbit. It is of advantage first to expose the infra-orbital nerve so that one may be sure by pulling upon the larger trunk that it is engaged in the hook. Therapeutically there is the same criticism to be made of this operation as of the resection of the Gasserian ganglion or any other neurectomy; it is not sure to relieve the patient of his painful attacks.

SCHWARTZ had an unfortunate result in attempting to remove the Gasserian ganglion. The accidental division of an artery delayed the operation one-half hour, and finally the ganglion was removed piecemeal. The operation was followed by a corneal ulcer and total blindness in that eye. The wound suppurated, and before the patient had entirely recovered the attacks of neuralgia came back as bad as ever.

PICQUE described the removal suprapubically under chloroform of a horsehair from the bladder of a girl aged fourteen. The patient had introduced the hair into the bladder, through the urethra, and several attempts were made to remove it but without success, even though the urethra was dilated for this purpose. The results in this and similar cases show that it is useless to attempt the removal of such articles through the urethra, and that it is wisest to remove them through an incision into the bladder. If the vagina is large enough to permit it, it is better to make the opening into the bladder through it rather than suprapubically.

At the session of October 12th CHAUVEL spoke of the "Diagnosis and Treatment of Lesions of the Intestine after Contusion of the Abdomen." A man was kicked in the abdomen by a horse and showed absolutely no

signs of intestinal injury. In particular it was noted that there was no muscular rigidity. Under these circumstances it was deemed unnecessary to perform laparotomy. Some hours later, however, the belly began to grow tense and tympanitic, and it was opened. There was a beginning peritonitis, which had its origin in three wounds of one loop of small intestine. These wounds were sutured and the patient recovered.

RECLUS had a similar experience with a man who had been kicked by a horse. There was no muscular rigidity and he counseled delay. The following day peritonitis set in and the autopsy showed a triple lesion of the intestine. In another patient whose abdomen had suffered contusion there was a distinct prehepatic resonance, and laparotomy was performed. Absolutely nothing was found. Reclus was formerly an advocate of the expectant treatment in such cases, but now holds that an immediate laparotomy should be performed after a severe blow upon the abdomen, such as the full kick of a horse, even though there are no symptoms whatever pointing to intestinal lesions.

At the Academy of Sciences, October 10th, BERGER called attention to the results which follow amputation of the upper extremity, including the scapula and most of the clavicle, for malignant disease of the upper end of the humerus. This method of treatment was recommended by him in 1887. He has performed it twice with success and the patients have been free from recurrence fifteen years and eighteen months respectively. If the subclavian artery and vein are tied the operation is easily performed without much hemorrhage. Freedom from recurrence has been obtained in about thirty-three per cent. of all cases which have been reported. This is a very satisfactory result, especially when it is compared with the result obtained by amputation at the shoulder-joint for malignant disease of the upper end of the humerus.

At the Medical Society of the Hospitals, October 21st, DUCASTEL gave an account of a patient who came to consult him for a perforation of the hard palate, which he at first supposed to be syphilitic. A more careful examination showed near the second right-molar tooth a little ulceration covered by a soft coat and surrounded by miliary granulations. The examination of the lungs further showed that the man was suffering from tuberculosis. There was no history of syphilis and no other lesions or scars which might be considered to be due to that disease. The diagnosis of tuberculosis was absolutely confirmed at the autopsy which was made some weeks later. Besides the advanced lesions in both lungs there was a large ulceration in the hard palate, in the margins of which were numerous tubercles with the bacilli of Koch. This situation for tuberculosis is rare, but is of importance on account of its great resemblance to syphilis in this situation.

At the Biological Society, October 22d, AUCHE and CHAVANNAZ reported that they had made a study of five cases of peritonitis following operation, and had found the white staphylococcus in the peritoneal fluid at the end of each operation. It was introduced by the operative act, since the fluid taken at the beginning of the operation was in every case sterile. In three of the cases drains were left in position and cultures of cocci were obtained from them in three to five hours after the operation. The number of cocci was by no means small. Injections of these cultures into the abdomens of rabbits did not produce any serious symptoms. All of the patients examined recovered. The conclusions drawn from these investigations were that the peritoneal cavity is infected at laparotomy far oftener than the results would indicate, and this in spite of painstaking efforts on the part of the surgeon to prevent it. The germs thus introduced are, however, not of a great degree of virulence as shown by the recovery of all the patients, as well as by the lack of symptoms in the rabbits that were inoculated by them.

At the Second Congress of Gynecology, Obstetrics, and Pediatrics, held at Marseilles, October 8th to 15th, SEGOND thus summarized the "Treatment of Extra-uterine Pregnancy":

For uncomplicated cases of less than five-months' duration, ablation by laparotomy is the operation of choice. For cases under five months complicated by free hemorrhage into the peritoneal cavity immediate laparotomy is indicated. Laparotomy is the best operation for hematosalpinx, the blood being so situated that fetus and blood-clot can be removed in one mass; also in cases of hematocele caused by repeated hemorrhages. It was formerly not considered necessary to operate upon encysted hematocele as a complicating factor in extra-uterine pregnancy. Opinion is still divided as to the course to pursue under such circumstances, but Segond much prefers an operation through the vaginal vault and an evacuation of the contents of the cyst, the operator proceeding with caution and gentleness.

If the pregnancy has passed the fifth month and there are no complications laparotomy should be performed and the cyst brought to the surface but not excised, as Nature will expel the placenta and the danger by following this method of treatment is less. If the pregnancy is complicated by hemorrhage the same treatment should be followed unless the bleeding is of such character as to render the ablation of the sac necessary. If the fetus has been dead some time operation should be performed at once, consisting of laparotomy with extraction of the fetus, the sac being left open for the expulsion of the placenta. If the fetus has recently died it is better to wait for a few days for the blood-vessels to shrink before proceeding to operation.

POZZI said that it was not necessary to advocate this or that operation. The surgeon should guide himself according to the conditions before him, and while he might choose to perform laparotomy in certain cases, a colpotomy would be better in others. The question to be decided is rather a topographical one than a hemostatic one. There is one incision which is little known and that is the lateral one, similar to that employed to expose the internal iliac artery. By this means one can reach a sac which is situated far to one side without opening the peritoneal cavity.

SAINT-BLAISE discussed the "Auto-intoxication of

Pregnancy." In general the body is constantly exposed to the effects of toxic materials in the food, as well as those which are formed in the body itself, notably the bile. There are two sorts of organs which protect the body from these toxic materials. First, the organs of transformation or arrest—the intestine, spleen, lymphatic glands, suprarenal capsules, the thyroid gland, and liver. Second, the organs of elimination—the intestine, skin, lungs, and kidneys. It is easy to understand that intoxication will take place when the production of toxic materials is increased, or the defensive power of the body is diminished. Both of these conditions are found in pregnancy, when the blood contains fewer red globules, and the respiratory power is lessened, as well as that of the heart; and finally the intestine acts slowly, and there are often constipation, dyspepsia, and abnormal fermentations. In the albuminuria which is often found in pregnancy the kidneys play only a secondary rôle. The real trouble is hepatic insufficiency. Other results of hepatic poisoning are digestive troubles, such as vomiting, dyspepsia and constipation, insomnia, alteration of the character, ptyalism, edema, pruritus, bronzed skin, pigmented spots, etc. More serious results are jaundice, puerperal mania, albuminuria, and eclampsia. All authors are not agreed that this last symptom is due to insufficient hepatic action, but this is the most reasonable view. If the action of the liver is sufficient, the patient is in no danger of severe attacks of eclampsia. The rational treatment of auto-intoxication rests upon the early diagnosis of the hepatic insufficiency.

MERY read a paper upon "Mixed Diphtheritic Infection." The mixed infection which has been most studied is that in which the streptococcus is present. The cases in which the staphylococcus is present are less serious and progress less rapidly than do the cases of streptodiphtheria. In the former the membranes are pulpy. When the coli bacillus is present the membranes are very thick and have a disagreeable odor. If the proteus is present the diphtheria is apt to be of a gangrenous type. Unfortunately, however, these differences are not sufficiently well marked to enable one to make a diagnosis from the clinical appearances. In all of these mixed infections, antidiphtheritic serum has the same effect upon diphtheritic processes as it does in uncomplicated cases. It needs, however, to be given in larger doses. Upon the growth of the associated microbes it has no effect, and it should not, therefore, be given when the condition of the throat is due to their action alone. Some good results have been reported from the use of antistreptococcic serum, and local treatment should be carried out whenever it can be done without injury.

For Dropsy of Cardiac Origin the following diuretic pill is recommended:

Pulv. scillæ Pulv. digitalis Caffeinæ citratis	aa . . .	gr. xxx
Hydrargyri chlor. mit.	. .	gr. v.

M. Ft. pil. No. XXX. Sig. One pill three times a day before eating.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON SURGERY.

Stated Meeting, Held November 3, 1898.

THE President, DR. EDWARD G. JANEWAY, in the Chair.

The chairman announced that the discussion of the evening was to be on

THE OPERATIVE TREATMENT OF HYPERTROPHY OF THE PROSTATE.

DR. EUGENE FULLER read a paper, entitled

THE RADICAL TREATMENT OF HYPERTROPHY OF THE PROSTATE.

He said that under the term hypertrophy of the prostate he includes only the cases of senile enlargement of the prostate which are so commonly seen. Just what the nature of this enlargement is is not always clear. It is partly glandular, partly muscular, but by no means in anything like unvarying proportions. At times, too, it is fibrous in character. It is a mistake to think that these enlargements bear much resemblance to each other or conform to a common type despite their being classed under the same head of prostatic hypertrophy. It is not always the middle lobe that by its enlargement causes prostatic symptoms. The lateral lobes may produce the same symptoms when hypertrophied. The obstruction to the passage of urine is not always at the same place. At times it is in the prostatic urethra, but at times it is due to intravesical projections that block up the urethrovesical opening. Dr. Fuller has seen a projecting mass the shape of the end of a banana, and in another case two finger-tip-like projections that blocked the urethral opening.

The size of the prostates that cause symptoms are also most variable. They may on removal weigh a pound, though one-half pound is large, and the usual weight is two to three ounces. There are a number of conditions that may simulate prostatic hypertrophy, notably affections of the seminal vesicles and atonic conditions of the bladder, so that cures under conservative medical treatment are readily open to the suspicion of falsity of diagnosis. Atony of the bladder that develops as a consequence of the overstretching of the viscus because of the insuperable obstruction occasioned by the hypertrophied prostate, used to be considered an extremely important factor in the case. Some even thought that it was the primary factor, and due to the advance of general sclerosis, and that its presence made a bad prognosis inevitable, but we now know better, and patients in whom complete atony of the bladder has existed get entirely well after the obstruction is removed.

In operating the only thing really worth considering is the radical removal of the obstructing mass. The objections to this so far have been that the old men in whom prostatic hypertrophy occurs stand an anesthetic badly, and also the loss of blood incident to a serious cutting operation. Both of these objections are met, Dr. Fuller

thinks, in operating by his method. The anesthetic is never given for more than fifteen minutes and serious bleeding is avoided by the use of serrated-edge scissors in cutting through the bladder for the enucleation of the prostate. He then described the operation he has employed since 1895 in twenty-seven cases. It is the suprapubic operation with a second slit in the bladder made with the serrated scissors to enable the operator to get at the prostate, a counter opening, a puncture being made through the perineum for drainage after the operation. Dr. Fuller does not tampon the bladder afterward because of the serious pain caused by the removal of the tampon, besides the danger of infection.

To avoid the danger of hypostatic pneumonia the patient is turned from side to side after a day or two, his shoulders are elevated as soon as practicable, and after a few days he is allowed to sit up in a chair.

The one contraindication to the operation is advanced arteriosclerosis with pipe-stem arteries. It is surprising, however, what hopeless-looking subjects survive the operation and are improved by it. Recently a colleague remarked, "Why operate on a corpse?" yet in six weeks the patient of whom the remark was made was up and around, feeling well.

Experience shows that this operation of suprapubic enucleation of the prostate is ever so much more satisfactory in its results than the old methods of cutting a trough through the prostate. Not only is there greater assurance of relief being afforded, but that relief will be more lasting. There is less danger of recurrence of urinary retention and the operation itself is less bloody.

As to the radical operation on the prostate by an incision through the perineum, as practised by Nichols and Alexander, it has the disadvantage of being slower and hence requiring the administration of much more of the anesthetic, always a serious consideration in these old patients. Then, too, owing to the nature of the tissues in the perineum it is much more bloody and time is required in dissection and in the securing of blood-vessels.

Dr. Fuller has operated on 27 patients by his method. Of these 5 were affected with arteriosclerosis so badly that the operation was contraindicated, but it was a last resource for the patient. Of the 5 two died. There were two deaths in the other 22 cases, and two cases of suprapubic fistulæ still persisting when they passed from observation. The results may be considered eminently satisfactory. As to other methods castration is unsatisfactory and mutilating. It does not always afford relief. Relapses occur. Its mortality in old men is almost if not quite as large as prostatectomy, and it does not furnish that rest for a diseased bladder so necessary in these cases. Bottini's operation would seem to be applicable only to milder cases, and to be open to the objection of causing dense cicatricial contraction and matting of the tissues, so that if prostatectomy should ever become necessary later it would be sadly complicated by the resultant scar tissue.

In Freudenberg's hands he had seen it relieve the frequency of urination though 200 c.c. of residual urine remained, so that often it was but palliative.

DR. WILLY MEYER read a paper on

PERSONAL EXPERIENCE WITH BOTTINI'S OPERATION FOR THE RADICAL TREATMENT OF HYPERTROPHY OF THE PROSTATE.

In addition to 5 cases reported before, Dr. Meyer has had 7 others. His third patient died thirty hours after operation but that is the only fatal case due directly to the operation. One patient died after a perineal section made immediately after the Bottini operation. A third died ten days later of sepsis. Of the 12 patients 6 were cured, that is, absolutely relieved of all their urinary symptoms; two were very much improved. The principle of the operation is certainly a good one, for it involves the mechanical removal of a mechanical obstruction. As to whether there might be recurrence from cicatricial contraction of the burned groove only Bottini himself has had long enough experience to answer the question with assurance and he has not seen a recurrence in twenty-three years of work with his method. In case of a relapse, however, there seems to be no reason why the procedure should not be employed a second time. One modification of Bottini's method Dr. Meyer has found advisable, that is, to do the cutting with the platinum knife at a white heat, not a red heat, the bladder not being empty as advised by Bottini, but full of some slightly antiseptic or aseptic fluid.

DISCUSSION.

DR. WEIR said that the two methods advocated were not generally known and practised by the profession and the account of them had been of great interest. He himself usually employs McGill's method and has obtained fair results with it. He said fair results advisedly, and in this work he thinks that the surgeon should be gratified with fair results, *i.e.*, if fifty per cent. of his patients are decidedly improved by operative interference. For some time, however, he has been impressed with the idea that the proper operation in the case is one of the enucleation operations, either Fuller's or Alexander's. The indication is to remove the obstruction and it is good surgery to do it thoroughly. Dr. Fuller's seemed to have the advantage of being shorter and less exhausting to the patient, requiring less anesthetic, and involving the loss of less blood. It is probable that this operation or some modification of it will eventually be adopted by all surgeons.

He could not help looking askance at Bottini's method. Twenty years ago and more it had been introduced with a great flourish of trumpets but had failed to fulfil the promises made for it. That was in the old days before antisepsis. Asepsis now with antiseptic surgery and greatly improved technic and instrumentarium had once more brought it before the public. Now, as twenty years ago, it is mainly one man who is enthusiastic about it. It does not seem, however, that surgeons will ever again be satisfied with the infliction of a wound that necessarily involves the sloughing away of tissues as do these cauterization wounds. They have been abandoned where they used to be most used, in the mouth and anus, and surgeons will not feel safe in a cavity so inevitably infective as the bladder in causing sloughs that will be

10 or 12 days in separating, with all the danger of infection always involved.

DR. HARTLEY thinks that Dr. Fuller's operation is often a very suitable one, and that it has many points to recommend it. There are cases, however, in which the perineal route is especially available, a modification of Nichols' operation being employed.

DR. ALEXANDER said he does not believe that either prostatectomy according to any of the present methods or Bottini's operation will always do good in hypertrophy of the prostate. We assume that we know much more about the prostate than we really do know, while in the matter of hypertrophy of the prostate especially there remains very much to learn. Dr. Fuller had said that the enlargement of the prostate is mainly due to overgrowth of muscular elements. A series of specimens carefully examined microscopically had convinced Dr. Alexander that the hypertrophy is mainly due to excess of growth of glandular tissue. The fibrous condition sometimes noted is due to secondary degeneration. The earlier in a case the specimen of prostate is examined the more completely glandular it is found to be. There is a question then whether we should not operate earlier than at present, not waiting for the imperative symptoms with bladder infection and general weakness that result. As for a benign tumor anywhere else, as soon as it gives symptoms remove it. The earlier the removal the better are the results as far as regards function and mortality. As regards radical operation, he is very well satisfied with his own method, though he concedes that others may get better results with theirs, the personal element having great weight in such cases. Two objections have been urged against it: that it is (1) long, (2) bloody. These objections come from a misunderstanding of the operation. Dr. Fuller had confounded his operation with that of Nichols of Glasgow. Twice already in print Dr. Alexander has insisted on the distinction between them. Nichols makes an incision across the perineum along the line from tuberosity to tuberosity. Alexander makes his as in ordinary perineal section, cutting at once into the membranous urethra and down to the apex of the prostate. From here it is not difficult after incising the capsule of the prostate to find the lines of cleavage in the organ and so enucleate it. Heretofore he has always made a suprapubic incision in order to push the prostate well down into the perineum. In two cases this summer, however, both of them thin subjects, he was able to accomplish prostatectomy without suprapubic incision, counter pressure being exerted through the thin belly walls.

The operation from the perineum has the advantage of leaving the muscular fibers in the trigone uncut, an extremely important consideration, for Dr. Alexander's anatomical specimens show that these fibers are useful for the complete emptying of the bladder. He has now done the operation some twelve times with excellent results, the patients being about in five weeks.

As to the patients with small prostates unenlarged as far as rectal palpation goes, and yet having the symptoms due to enlarged prostates, these were often cases of enlargement of accessory prostates in the trigonal region, a small tumor here being sufficient to block the urethrovesical opening. Situated here, too, they interrupt and interfere with the waves of muscular contraction in the bladder and so prevent its proper emptying. To these accessory prostates are really to be attributed the symptoms at times attributed to small fibrous prostates. Our best hope as to improvement in the treatment of prostatic hypertrophy lies in a better knowledge and deeper study of the anatomy and pathology of the part.

Dr. Fuller in closing the discussion said that the suprapubic route must be the one of election because of the facilities it gives for the control of hemorrhage, always a serious thing in operations in this region. Objections against it there could be none. By never permitting the suprapubic incision to be touched after operation danger of infection is greatly lessened and infiltration into the space of Retzius avoided.

DR. WILLY MEYER in concluding the discussion said that the objection to the Bottini operation because of the liability of the cauterized tissues to contracture afterward, seems unfounded. Experience has not demonstrated that it occurs and it may be reasoned that the passing of a good stream of urine at regular intervals keeps the opening patulous. No method of operating for prostatic hypertrophy is perfect, but certainly in men of eighty to ninety, or even younger ones when feeble, the simple manipulation of Bottini's method seems preferable to a cutting operation.

After the President's announced that Professor Wm. H. Welch of Baltimore would address the Academy at the next stated meeting, the session adjourned.

THERAPEUTIC HINTS.

Formula for a Diaphoretic Powder.—

℞	Pulv. camphoræ . . .		gs. ⅓—1⅔
	Pulv. opii		gr. ⅓—½
	Potassii nitratis . . .		gr. iii—v
	Sacchari		ʒ ii.

M. Ft. chart. No. I. Sig. To be taken in a cup of tea before retiring.—*v. Graefe.*

For the Asthenia of Infantile Gastro-intestinal Affections the following stimulating and nutritive mixture is recommended for rectal injection:

℞	Quininæ hydrochlorate, Asafœtidæ }	aa . .	gr. xv
	Tinct. moschi		*m.* xv
	Aq. dest.		℥ iv
	Yolk of egg		No. i.

M. Sig. For three or four injections in twenty-four hours.—*Jede.*

For Angina Pectoris.—When given in the following mixture nitroglycerin is said to afford relief very quickly. The dose may be increased as the patient grows tolerant of the drug.

℞	Nitroglycerin		gr. iii
	Tinct. capsici		ʒ ss
	Spiritus rect., Aq. menthæ pip. }	aa . . .	ʒ iii.

ORIGINAL ARTICLES.

INHALATION OF OXYGEN IN ACUTE AFFECTIONS OF THE LUNGS.[1]

BY ANDREW H. SMITH, M.D.,
OF NEW YORK.

INHALATIONS of oxygen are now very commonly resorted to in chest affections when the dyspnea becomes marked. The use of this agent was introduced into this country by the writer in 1860. By experiments on animals he had demonstrated that by enriching the atmosphere with additional oxygen, life could be maintained for long periods under conditions of tracheal obstruction that would be immediately fatal in common air.[2] In an essay published in 1870, he showed what was then generally disbelieved, that the inhalation of even pure oxygen is harmless,[3] and urged the addition of the gas to the inspired air in a variety of diseases in which it had been found useful by European practitioners. The introduction of compressed oxygen in cylinders for commercial purposes facilitated the use of the gas in sufficiently liberal quantities to test its real value as a therapeutic agent, and for the last twenty-five years it has occupied a prominent place in the treatment of respiratory affections and especially pneumonia.

The result of the use of oxygen in cases of respiratory difficulty will depend largely upon the exact mechanical conditions present. If the obstruction is partial, and is of such a nature that air, once having passed it, can then have unrestricted access to the alveoli, an almost normal respiratory relation can be reestablished by adding enough oxygen to the respired air to compensate for the diminished quantity of the latter. But if the obstruction is complete, or practically so, in any part of the lung, or if it extends into the air-cells themselves, the case is quite different. Such a condition involves a lessening of the respiratory surface, which means much more than a mere narrowing of the air-passages.

It is essential to remember that normal respiration requires that a normal amount of oxygen shall be brought into relation with a normal quantity of blood. Now we possess the means of remedying to a certain extent a deficiency of air, since we can make a reduced volume contain the full amount of oxygen, but we have no power to act in a corresponding way upon the blood, for it cannot be made to take up an excess of oxygen in one part of the lungs to compensate for a deficiency in another. Suppose, for instance, the lumen of the trachea should be diminished experimentally one-half, we could double the proportion of oxygen in the air and the respiratory demand would be satisfied. But suppose that instead of narrowing the trachea to one-half its transverse area we should cut off one-half the supply of blood to the lungs by clamping one of the pulmonary arteries, the resulting dyspnea now would not be relieved by any amount of oxygen added to the respired air, for the reason that the blood circulating in the other lung would refuse to absorb more than the usual proportion of the gas, and the process of aeration of the blood would be only half accomplished. We might vary the first experiment by leaving the trachea unobstructed but closing entirely one of the primary bronchi. This would cause about the same reduction of the quantity of air inhaled, but at the same time it would throw out of use one-half of the pulmonary capillaries. In this case, as in the last, the addition of oxygen would fail to give relief, and for a similar reason.

It is not strictly true that when a restricted supply of air is compensated for by the addition of oxygen, the normal respiratory conditions are reestablished. To be entirely satisfactory the respirations must have the normal amplitude. This is necessary to give the free play to the lungs which is required for a proper distribution both of the air and the blood to all parts of the pulmonary structure. But the trouble from this source is not urgent, and can very well be tolerated for a considerable time.

Applying these considerations to the conditions occurring in acute respiratory disease we find them amply sustained by clinical results. The dyspnea of membranous croup is at once relieved by oxygen if enough be given to compensate for the diminished supply of air. Once get the required amount of oxygen past the obstruction and the respiratory distress ceases. The same is measurably true in bronchitis.

[1] Read by title before the American Climatological Association, September 1, 1898.

[2] "Oxygen Gas as a Remedy in Disease." Prize Essay of the Alumni Association, College of Physicians and Surgeons, New York.

[3] Among other experiments a number of mice were confined under a bell-glass, into which flowed a constant stream of pure oxygen. In this way the products of respiration were removed as rapidly as formed, and the purity of the respired gas was maintained. The experiment was continued for ninety-six hours, during which the animals took their food, arranged their bedding, and behaved in every way as mice in confinement are accustomed to do. After the conclusion of the experiment they were kept for several days and remained apparently in perfect health.

In this affection the secretion is rarely in sufficient quantity to entirely obstruct even the smallest tubes, and a way is left open by which the oxygen can reach the alveoli. There it meets an adequate supply of blood and the process of hematosis goes on in a fairly normal manner. But in pneumonia the case is entirely different. Here the air cells become filled up with the exudate and access to the respiratory surface is barred. The situation is similar to that in the last experiment, and so much of the dyspnea as depends upon the consolidation will remain in spite of oxygen used ever so freely. This is not to say, however, that no good comes from its use in lobar pneumonia, as there is almost always a certain amount of bronchitis or edema present at the same time, which adds more or less to the respiratory embarrassment.

Its value in these diseases rests on a broader foundation than is immediately apparent. It is not alone that it tends to avert suffocation. Indeed, it is very seldom that a patient, with pneumonia, for example, dies directly from deprivation of oxygen. As a rule, before death from actual suffocation takes place the heart, and particularly the right heart, gives out, and the fatal result is from asystole. This exhaustion of the right heart is a gradual process, and is brought about by the increased muscular effort required to propel the blood through the affected lung. The pulmonary ischemia is made up of two factors, one of which is the obstruction of the vessels, and the other and a very important one, the sluggishness with which blood not duly aerated circulates even through unobstructed capillaries.

It is in the relief of this latter condition that oxygen is most valuable. The moment the arterialization of the blood is improved the circulation becomes easier and the labor of the right heart is lightened. It is a serious error, however, to defer the use of oxygen until the dyspnea has become urgent. By its timely employment the cardiac force can be conserved, and congestion of the unaffected lung territory is in a great measure prevented. But inasmuch as blood even under the most favorable conditions will not take up an excess of oxygen, if we delay too long, and suffer the access of air to become too much restricted, no addition of oxygen acting upon the limited quantity of blood circulating in the lungs will suffice to restore the balance and regain the ground which has been lost.

While the results obtained from oxygen in the croupous form of pneumonia may not be so favorable as in the bronchial, still it is capable of rendering valuable aid in a large proportion of cases. A common source of disappointment lies in reserving its use until a period when, for reasons already considered, its value is comparatively limited. Even in those cases it may serve to bridge over a time of special danger, but the best results are obtained when it is given more or less freely from the moment that it becomes clear that the case is one of more than moderate severity. Its good effects will be shown in lessened frequency of the pulse and respiration, a better color of the face and lips and fewer moist râles in the chest.[1]

In spasmodic asthma it would seem as if the conditions were such as to insure most satisfactory results from the use of oxygen, and in practice relief is generally obtained from it almost immediately. But there are cases in which it does very little good, if any. Repeatedly witnessing such paradoxical results has led me to ask myself whether there may not be a form of asthma in which the spasm includes the blood-vessels of the lung as well as the air-tubes. I cannot otherwise explain why cases apparently similar to others which yield at once to the gas should be entirely rebellious to its influence.

In using the compressed gas, it is allowed to escape from the cylinder through a wash-bottle, the valve being so adjusted that the gas bubbles gently through the water. From the wash-bottle the gas is carried to the patient's mouth through a flexible tube provided with a mouthpiece of glass or hard rubber. If the patient is in a condition to hold this in his mouth no more will be required. Otherwise, it must be held by an attendant in such a position that the escaping gas will be drawn into the lungs with the current of inspired air. A still better way, especially if the patient is comatose, is to pass a small, flexible catheter through one nostril into the nasopharynx, and to connect this with the wash-bottle. In this way very little of the gas is wasted. If it is desired to add any volatile substance to the gas inhaled, a solution containing it may be made to replace the water in the wash-bottle.

There is no advantage in a lavish use of the gas, as the blood will take up only a very limited amount. If it escapes too freely it adds to the sensation of breathlessness, as is the case when one faces a strong wind. Only pure oxygen should be employed. The addition of nitrous oxid with the idea that it is more soluble in the blood should be condemned, as the oxid is useless for the purpose of respiration, and interferes with the proper interchange of gases within the lungs.

In pneumonia the indication for a resort to oxygen is present as soon as the respirations exceed thirty-five per minute, and earlier than this if mucous râles develop outside of the area of consolidation, or

[1] For a full discussion of this point see an article by the writer in the *New York Medical Gazette*, December 18, 1870.

if the lips assume a dusky hue. Under these conditions it may be given continuously or during a prescribed number of minutes in each hour.

GASTRIC ULCER.

BY A. L. BENEDICT, M.D.,
OF BUFFALO, N. Y.;
PROFESSOR OF PHYSIOLOGY AND DIGESTIVE DISEASES IN THE DENTAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

UNDER the word ulcer must be included at least three types of gastric lesion. The type most closely analogous to ordinary external ulcers consists in the erosions found in acute toxic and traumatic gastritis. So-called hemorrhagic erosions, due to back-pressure of blood and most commonly found in cases of chronic gastritis dependent on hepatic sclerosis, do not belong to this type but are rather to be considered a form of the second type or as a separate class. The second type is the latent ulcer of the middle-aged and elderly, which usually gives no diagnostic symptoms and is discovered only at autopsy. The third type is the one which departs most of all from the general conception of the word, but is the one which is usually meant when no specification is made to the contrary.

Peptic, round or rodent ulcer has been ascribed to two conditions, hemorrhagic infarction and neurosis. The former theory is more satisfactory and tangible as a theory, but it is rendered improbable by the fact that persons who have gastric ulcer are seldom those in whom one would expect to find any of the pathologic states on which infarction depends and, *vice versa*, persons in whom serious circulatory conditions are in progress do not often exhibit signs of peptic ulcer. It is probable, however, that the second type, of latent ulcer, does occur more or less frequently from hemorrhagic infarction. The use of the word neurosis is always a confession of ignorance and many writers who have used it most learnedly have failed to explain why a nervous state should cause one part of the gastric wall to lose its vitality, and to be acted on by the gastric juice as if it were so much meat in the stomach. Perhaps it may be assumed that there is a local vasomotor spasm which temporarily shuts off nourishment from an area and allows its digestion. There is little dispute but that the actual formation of the ulcer depends on the digestion of a part of the gastric wall, however we may explain the lessening of the normal resistance to digestion.

As in the case of some forms of cancer it can be recognized quite clearly that the cause which determines the special location of the disease is largely traumatic or mechanical. Stoll and other Germans have shown that in men the pylorus and its immediate vicinity is the area of preference of gastric ulcer in sixty per cent. of all cases, while the lesser curvature is involved in forty per cent. of all cases occurring in women. The fact that no other part of the stomach wall shows any particular predilection in either sex and that there is so marked a sexual disparity plainly signifies that there is some physiologic underlying cause. It is explained that the pylorus bears the brunt of the irritation by food-particles and that it is also pressed upon by the liver at each descent of the diaphragm, in men, while in women the lateral constriction of corsets and waist-bands prevents the lesser curvature from getting out of the way of the descending diaphragm. On the other hand, it is an open question whether the bodies upon which the statistics were based represented a class of society in which corsets are much in vogue. This again brings up a still unsettled question as to whether there is any difference between the male and the female type of respiration, not directly explicable by differences in clothing. The writer would suggest that, possibly, the difference is due to the well-established fact that women are more liable than men to moderate dilatation and ptosis of the stomach, whether they wear corsets or not, and that a sagging stomach would escape the pressure of the diaphragm on its pyloric end.

Stoll's studies also seem to disprove the commonly accepted statement that the typical victim of gastric ulcer is a young, chlorotic, overworked woman. Allowing for the fewer persons living to an advanced age, as compared with the young, and for the fact that after the age of fifty, female mortality is lower than male, Stoll's statistics from several thousand observations indicate a greater predisposition on the part of the middle-aged and elderly and very little sexual difference. But it must be remembered that such statistics as these are based rather on the pathologic than the clinical conception of ulcer; that, in many instances, the ulcers are avowedly of the second or latent type and not suspected *ante-mortem*, and, if it were not for the carefulness of German observers in general and of those quoted in particular, one might question whether all these ulcers were really formed *ante-mortem* and whether they did not represent *post-mortem* softening, which has been described as a disease of the stomach within the period covered by the observations of Stoll and those from whom he quotes.

The present teaching points to a close causal relation between superacidity of the gastric juice and gastric ulcer. But there are obvious objections to making a diagnostic use of this relation, since a stomach in which the existence of an ulcer is suspected is the very one in which interference by the tube is most contraindicated. Moreover, there is

very little support for the idea that there is a constant superacidity in cases of ulcer, even limiting the use of the word *constant* to periods of the height of digestion. Stoll, in a personal letter, states that superacidity does not exist in more than fifty per cent. of cases of gastric ulcer, while the study of his report of about ninety cases gives the conclusion that only twenty-five per cent. were marked by superacidity, while an equal proportion showed a real deficiency of acid.

The diagnosis of the third class of gastric ulcer occasions no difficulty. Erosions may be assumed to be present in every case of corrosive poisoning, and if, in comparatively rare instances, the assumption happens to be wrong no harm is done. The diagnosis of the second class of ulcer is easy for the reason of its extreme difficulty. One must consider the possibility of latent ulcer in cases of dilatation and gastroptosis, of chronic gastric catarrh and its ultimate stage of anadenia, and particularly when hepatic sclerosis or heart disease causes back pressure in the venous radicles of the stomach, but it is almost always impossible to state whether an actual solution of superficial continuity exists or not, nor is it necessary to modify our treatment materially according to our verdict for or against the probability of such an occurrence.

It must be conceded that peptic ulcer may exist without marked hemorrhage, and that such cases are usually overlooked. Among the many symptoms of gastric ulcer of the first class that have been mentioned by clinicians, pain is the only one which is at all characteristic, and there is absolutely nothing except hemorrhage which is of diagnostic value either by its presence or absence. Thus the diagnosis of peptic ulcer is essentially a localization of the source of a hemorrhage, appearing at the mouth or anus, or both. Most medical students graduate with the idea that it is a comparatively easy matter to diagnose between hematemesis, hemoptysis, and local bleeding from the nose and throat; that only ignorance or carelessness can occasion error. In many instances considerable difficulty attends the localization of the hemorrhage. For example, a young man was seized suddenly with a copious hemorrhage from the mouth, with neither gagging nor coughing except after the blood had begun to flow, and while in apparently perfect health. He had one of the best developed and most muscular chests that I ever saw, was well nourished, and of good complexion except for the sudden pallor. There was no history of strain which might account for a pulmonary or other apoplexy. I examined him first for local causes of bleeding in the mouth, pharynx, and nose without success. Physical examination showed a good-sized cavity in the left lung, and the subsequent course of the disease confirmed the diagnosis of consumption previously undiscovered. The following case remains undecided:

On March 26, 1897, J. H. H., aged twenty-nine years, consulted me on account of gaseous dyspepsia, with constipation and cardiac irritability hardly amounting to palpitation. He gave a fairly typical history of malaria during the previous year cured by quinin without medical attendance. His domestic relations were unhappy, and he was working from twelve to fifteen hours daily, where he had to be constantly on the alert to entertain customers. He was smoking and drinking tea rather excessively, and was suffering from insomnia. The heart and liver were normal, the spleen was moderately enlarged, and the stomach was in a state of ptosis, reaching to one-fourth of an inch above the umbilical equator. I did not examine his lungs as there was nothing to call attention to them. The liability to gastric ulcer was considered on account of the depressed and excitable state of the patient, but hydrochloric acid was given on account of the evident fermentation and the lack of effervescence with soda at the height of digestion. It is not necessary to detail the treatment contemplated, as the patient became disgusted after four-days' treatment without cure and sought another physician. Two months later he had a violent hemorrhage and died in twenty minutes, before medical aid could be summoned. During this time he had coughed somewhat, and his physician had made a tentative diagnosis of tuberculosis with possible cavity, though the physical signs had been doubtful. An autopsy was not allowed. Careful questioning of his brother, who was with him at the time of death, elicited nothing definitely diagnostic as to the source of bleeding, but the blood was described as coming in large quantities and without symptoms of choking as would be expected if it had issued through the air passages.

Even if the diagnosis of hematemesis can be made, one must still choose from a number of conditions. If moderate, it may be due to erosions or previously latent ulcers, perhaps depending on hepatic sclerosis. The bleeding of a cancer, either of the stomach or esophagus, is usually gradual, and the blood becomes black before its appearance, and is not present in alarming quantities, but a cancer may ulcerate into a vessel and cause a flood of blood. Age is not a positively diagnostic factor. The writer has recently attended and witnessed the autopsy on a man aged thirty-two years who had a cancer of the cardia and esophagus. If we accept Stoll's statistics as applicable to peptic ulcer in the strict sense the period of greatest frequency is the same for both ulcer and cancer. Massive hemorrhages may occur from ruptured varices of the cardia and esophagus, usually due to hepatic sclerosis. A case probably of this nature was reported by the writer two or three years

ago and, at that time, about thirty-five cases were on record. The writer has had under treatment for seven years a woman who has had prolapsed uterus, hemorrhoids, cerebral apoplexy, frequent subcutaneous rupture of veins, and several small hemorrhages in which the blood has escaped through the mouth, the exact site of the bleeding being unknown. A general state of angiosclerosis seems to exist, the patient being of the class of "lady tipplers" who become alcoholic as a result of invalidism. The most remarkable source of hematemesis that the writer ever saw was reported nine years ago, the diagnosis having been made only at autopsy. A large ovarian cyst, the presence of which was obvious, had become adherent to the colon, rupture had occurred into the bowel below the ileocecal valve and blood filled the entire alimentary canal, the patient having had hematemesis and having passed tarry stools for a week before death. Duodenal ulcer is comparatively rare. A diagnostic differentiation has been proposed, according as the hemorrhage appears at the mouth or the anus, but the differentiation does not hold good either for or against either condition. Fortunately, the question is rather of scientific than of therapeutic interest.

Of late years the treatment of gastric ulcer has turned too much on the matter of acidity. The two following cases will illustrate the lack of connection, though it must be granted that superacidity is to be dreaded in all cases of ulcer:

Margaret X., aged twenty-three years, single, gave a distinct history of hematemesis the year previous and said that her physician had diagnosed gastric ulcer. Her present complaint was gastric fermentation with every symptom of subacidity, and the examination of the stomach contents at the height of digestion after a light test-meal showed absolute lack of hydrochloric acid by resorcin and sugar.

Mr. L., a young professional student, illustrated the opposite condition. He had no failure of digestive power; on the contrary, his appetite was increased. At the height of digestion, after most of his meals, he had suffered from pain in the epigastrium, which would be relieved by drinking water or eating again. This condition had existed for about a week to such a degree as to occasion much discomfort. Previously it had not been so noticeable. The writer's effervescence test showed marked acidity six hours after a hearty meal when the stomach should have been and appeared to be empty. A month later (the patient lived out of town and could not call as often as was desired) the same test was marked four and one-half hours after eating in spite of sedatives and restriction of chlorids. This patient, an unusually intelligent observer, noted the symptoms of superacidity for a period of five or six weeks with never more than two-days' freedom from local pain and often with the occurrence of pain after every meal, but he could find no indication of blood in the stools nor was there other evidence of the actual development of an ulcer. There was also entire freedom from the signs and symptoms of fermentation with excessive development of organic acids. The writer has never observed a case in which organic acids could be supposed to cause audible effervescence with soda.

The following typical case of gastric ulcer is reported in detail for the sake of emphasizing the treatment:

Miss M. P., American, seamstress, aged twenty-one years, was treated in the spring of 1896 for subacid dyspepsia, confirmed by analysis of the gastric contents and by repeated absence of the effervescence test, and made a good recovery. She gave a history of similar attacks during preceding springs. On January 15, 1897, she appeared at my office looking like a ghost, panting for breath and complaining of palpitation of the heart, which was beating 130 times a minute. She had taken a street-car to within a thousand feet of the office. Her history was that she had been perfectly well until two days before, when she became pale, weak, and dizzy, but persisted in working, and had rallied in strength. That day she had vomited something black and had passed a tarry stool. Morphin, $\frac{1}{4}$ of a grain, and atrophin, $\frac{1}{100}$ of a grain, were given by hypodermatic injection and after a brief rest the patient was taken home in a closed sleigh surrounded by heaters. After she had been put to bed 30 minims of fluid extract of ergot was administered hypodermatically, the alcohol being first driven off in an extemporized water-bath and the residue diluted with boiled water. She was directed to take nothing by the mouth until I saw her again. The next morning, feeling better, she ate a small piece of bacon. Half an hour later the soda test showed considerable effervescence. Her urine contained neither albumin nor sugar, but was loaded with indican, signifying that the bowels were filled with putrescent material, presumably blood. In such cases the indican test is of considerable diagnostic value. The day's routine included two doses of 15 minims of ergotole, two nutrient injections of 1 egg and 7 ounces of milk, and at night a morphin and atrophin tablet. Regarding the ergotole I would like to say that it is an excellent preparation but that the claim that it is less painful for hypodermatic use than other preparations of ergot has not been substantiated in my experience. The only preparation of ergot which does not occasion considerable discomfort is the so-called ergotin, of which the dosage seems to be a matter of guesswork.

Early in the morning of January 17th, four days after the beginning of symptoms of loss of blood, the patient vomited about ten ounces of liquid containing dark-red clots. Bits of ice had been allowed during the preceding twenty-four hours. Morphin, $\frac{1}{4}$ of a grain, and ergotole, 12 minims, were given hypodermatically in succession. At nine o'clock the patient vomited again, but there had

been no fresh bleeding of any consequence. At 11 o'clock the morning nutrient enema was given, preceded, as all such enemata must be, by a douche of plain water to clear the rectum. The stools brought away by the douches or passed spontaneously were at first tarry, becoming normal after a week. At 1 P. M. vomiting occurred again, with only a few small black specks of blood. Morphin and atropin were given by the mouth. At five o'clock the ergotole was repeated. At 7 P. M. the patient vomited seven ounces of black, watery stomach contents. This emesis was apparently provoked by the water enema preceding the evening nutrition.

During the next day the patient had about ¾ of a grain of morphin on account of nausea and 80 minims of ergotole. Fifteen grains of bismuth subcarbonate was given toward evening. In the evening vomiting occurred of dark fluid, apparently containing little masses of blood. Microscopically these proved to be bismuth (sulphid), although red and white blood-cells were also present. The stomach contents were acid by benzo-purpurin, the most sensitive of the anilin dyes, but did not react to resorcin and sugar. Starch and sugar were absent, as would be expected. Albumin, albumose, and peptone were each present in small amount, probably from digestion of the blood.

After this there was no further hemorrhage, the use of morphin was discontinued, and the ergotole was reduced to 15 or 30 minims daily. Beginning January 19th, 2½ drams of a ten-per-cent. mixture of bismuth hydrate was given four times daily. After January 21st, 15 minims of tincture of the chlorid of iron was added to each nutrient enema on account of the anemia. On January 23d the German method of applying flaxseed-meal poultices to the epigastrium was instituted. Hemic murmurs were heard for a few days, but had disappeared by January 26th. The pulse had varied between 85 and 100, and the temperature had not been above 100.5° F.

On January 28th, feeding by the stomach was resumed, bread and milk being first given, then oysters, meat, and eggs. In such cases easily digestible food should be given, but it must be "hearty"; that is, composed largely of proteids which will tax the gastric juice and leave no excess of acid and pepsin to digest the gastric wall. On January 30th the urine for twenty-four hours amounted to 24½ ounces, and was normal except for a moderate excess of indican and a small amount of urea, only 11.9, the estimated normal under the circumstances being about 18. On February 7th free uric acid was present. After that date the urine was once faintly alkalin, with precipitation of phosphates, and once traces of albumin and globulin were found.

On February 11th the patient was discharged from active treatment, but continued for some time under general hygienic measures, including, especially, gymnastics to increase the chest expansion and to correct a rotary-lateral curvature of the spine. Iron and arsenic were also given and a long rest was insisted upon. Fortunately, the patient was working rather from an independent spirit than from necessity.

In these cases the indications are first to check the hemorrhage, then to allow the ulcer to heal, and finally to restore the digestive and general tone. Local styptics do more harm than good, and the stomach must be kept in a state of almost absolute physiologic rest. Ice is used rather as a compromise with the demands of the patient than with the hope of controlling hemorrhage. Much of the nausea which threatens to cause a renewal of hemorrhage is doubtless due to the morphin given at the beginning, but its use is scarcely preventable, and, for once, one must resort to the plan of *similia similibus curantur*, and control the nausea for a few days with more morphin. Ergot at present is the favored constrictor of blood-vessels. Some form of insoluble antiseptic astringent is indicated as a dressing for the ulcer, and the mixture of freshly precipitated bismuth hydrate is, in my opinion, an ideal one. However, the subcarbonate may be used with good effects. During the administration of bismuth it is important to distinguish the black color of the stools and vomitus from that due to digested blood. The semicrystalline appearance of bismuth sulphid under the microscope is easily learned, though difficult to describe. A black coating on the tongue indicates the presence of hydrogen disulphid, and unless eggs or beans have been taken by the mouth this is hardly ever present except from the action of the bacillus coli communis in the stomach or duodenum. It is an interesting speculation as to whether the bacillus has actually colonized in the ulcer. It may be well to combine a more powerful gastro-intestinal antiseptic, like salacetol, benzonaphthol, or the like, with the bismuth. Menthol and similar stimulants of local circulation should be avoided as long as danger of hemorrhage exists.

Addendum.—Since writing the above, my attention has several times been directed to the importance of knowing whether blood is or is not present in various secretions and excretions. There is no satisfactory test. I have known the test with guaiacum to fail after the intentional addition of several drops of blood to urine. Of at least negative value is the hematoidin reaction obtained by acidifying with acetic acid and extracting with ether, when a brownish color should occur. In a recent case the diagnosis of cancer of the bowel had been made largely on account of the belief that blood was present in the stools. This test showed its absence. The appearance of a reaction may be due to bile pigments.

THE CAUSE AND TREATMENT OF BUBO.

By GEORGE T. HOWLAND, M.D.,
of Washington, D. C.

Bubo may be caused by chancroids, gonorrhea, chancroid and chancre or mixed infection, chancre, trauma, or by non-venereal elements. This classification represents the order of frequency, as it has occurred in the writer's practice.

A chancroidal bubo is by far the most frequent complication of chancroid. Sturgis[1] states that in 249 cases of chancroids bubo occurred in 71, a percentage of 28.5. Szadet[2] reports 1084 cases, among which were 274 buboes, a percentage of 25.1. Martin[3] records 19 per cent. in 163 cases in his hospital service, while in private practice there was only 5 per cent. of buboes in all cases of chancroids treated. In the writer's record of 156 cases of chancroid, bubo occurred in 53, a percentage of 33.9. These figures are taken from dispensary work, while in private practice my percentage has been less than 3 per cent.

While buboes may be double or single, the majority of them are single. Sturgis in 71 cases of buboes records 54 single and 17 double. Perry[4] in 36 buboes records 27 single and 9 double. In the writer's 53 cases, occurring in dispensary work, 43 were single and 10 double. In private practice all buboes due to chancroids have been single. The writer believes that there is no source so pronounced a factor in the cause of chancroidal buboes as uncleanliness.

Luca[5] holds that simple bubo is due to the ordinary pyogenic bacteria, while the ulcerating bubo is the result of the direct action of the specific microbe developing inflammation only after opening, because the microbe is aerobic. Ducrey,[6] the father, so to speak, of the bacilli found in chancroidal sores, states that he believes that chancroidal buboes are the result of destructive action upon the glandular tissue of the chemical products engendered by the micro-organism of soft chancre. He further states that the bacilli of chancroids can be found in the pus of chancroidal buboes.[7] These views have been upheld by Welander,[8] Krefting,[9] Unna,[10] and other observers. The latest observations on this subject come from the pen of Deutsch,[11] recording 66 cases of suppurating buboes, 37 of which occurred with chancroid, and 29 with either chancre or a mixed sore. Of the 37 cases occurring in a complication of chancroid, inoculation upon the abdomen was successful, with the production of a typical chancroid in three instances only. In these three cases the pus from the buboes showed the presence of the Ducrey-Krefting bacillus. The pus obtained from the buboes could be classified under one of three heads: Sterile pus; pus containing streptococci or other pus-producing micro-organisms; pus containing the Ducrey-Krefting bacillus, either with or without the admixture of other micro-organisms.

It was found that buboes containing sterile pus healed within a short time and the auto-inoculations were unsuccessful; seven to ten days usually sufficed for healing to take place. Those buboes under the second heading took a longer time to heal, fourteen to twenty days, being longer in the cases of strumous individuals, and inoculations in these cases were unsuccessful. Those buboes containing the Ducrey-Krefting bacilli took a much longer time to heal, and were most difficult to treat. Auto-inoculation in these cases was successful. This careful bacteriological and experimental study on this subject makes Deutsch's article one of the most important and valuable contributions to the study of buboes that has appeared in recent years. On the other hand there are many authors who do not believe in the buboes of chancroids being caused by micro-organisms. Taylor[12] says, "When I say in some cases in which there has been absolutely no chancrous pus-contamination of the abscess, dirt, uncleanliness, and carelessness have caused the suppurating process to become virulent and to assume all the features and qualities of a typical chancroidal abscess."

White and Martin[13] say that the direct cause of bubo is not clearly formulated. The destructive adenitis is not due to the action of micro-organisms upon the gland. Cultures and auto-inoculations made with the discharge of buboes give negative results, and microscopic examination of such discharge fails to show bacteria. The degeneration of the glands is probably owing to the presence of a chemical irritant absorbed from the ulcerating surface.

Of the 156 cases of chancroids occurring in the practice of the writer, chancroidal buboes were present in 53 instances. Of these, 40 presented pus and were opened. Three were simple enlargements of the gland, and never reached the stage of pus formation. Of the remaining 10, 6 had broken down and were in a bad condition when the patients presented themselves for treatment. Four became infected at or after the operation. Out of the 40 cases of buboes, the pus was examined in 20 by the microscope, by culture-media, and by reinoculation, results being negative in all instances. In the ten cases of virulent buboes the pus was examined in all, and gave positive results of the presence of the pus-forming micro-organism by the microscope and by culture-media. Reinoculation was not successful. Nothing resembling the Ducrey-Krefting bacilli was discovered.

GONORRHEAL BUBO.

Taylor[14] states that an adenitis following a gonor-

rhea is the result of the too actively aggressive treatment of gonorrhea or of bodily strain. Lydston[15] believes that a bubo complicating a urethritis is due in every instance to secondary lymphatic infection by pus-microbes. Finger[16] states that Brockhard found streptococcus pyogenes in the pus of an acute suppurating adenitis complicating gonorrhea, and it is, therefore, probable that we sometimes have to deal with a mixed infection. Perry[4] claims that it is a somewhat rare complication and when it occurs it is probably due to the absorption of a chemic poison, the result of a mixed infection.

A short time ago I had a very interesting case of gonorrhea complicated by a bubo. The urethral discharge contained the Neisser coccus. At the time of consultation it was the third week of the disease, and the patient noticed a small lump in the left groin. The bubo pointed and had to be opened. The urethral treatment consisted of chlorid of sodium, 1 grain to the ounce, injected four times daily. The discharge was examined daily, and as the bubo enlarged the germs were disappearing from the discharge until the bubo was opened. After this the urethral discharge ceased. The bubo was treated carefully, and healed within ten days. The pus from the bubo was carefully examined. The results were negative. It hardly seems possible that the salt solution used as an injection exerted any influence upon the course of the disease, especially upon the urethral inflammation. The bubo may have been caused by the active and perhaps the severe treatment that the patient received at the start; he was being treated by the hot irrigation of permanganate of potassium four times daily. The patient was not in a debilitated condition when under treatment.

The percentage of gonorrheal buboes in my practice is 2.3 per cent.

CHANCRE AND CHANCROIDAL, OR "MIXED CHANCRE."

I have seen but ten cases of the "mixed chancre," all of which were complicated by buboes. In all but two cases they were double. The two exceptions were followed by the most virulent suppuration, but as soon as the patient was put on an antisyphilitic treatment they responded quickly. These two cases, I believe, were the result of a too active and severe treatment of the mixed sore.

CHANCRE BUBO.

Chancroidal buboes are invariably double, and it is rare for them to break down and suppurate. I have seen four cases of syphilitic buboes which suppurated. This was due in each instance to the irritation and inflammation caused by the cauterization of the initial lesion with nitric acid. This occurred in the clinic of a celebrated foreign syphilographer.

TRAUMATIC OR NON-VENEREAL BUBOES.

My records show 20 cases of buboes of traumatic origin. In every instance a careful examination and inquiry was made into the history of the patient and the result was that venereal causes were excluded. In only 6 of the cases was the general health poor. In none was there an abrasion or sore on the penis. In 2 cases there was a distinct irritation in the foot. One was an infected toe from an ingrowing nail, and the other from an abscess of the sole of the foot. No suppuration took place.

Godding[17] says that non-venereal buboes are quite common in the British navy, both in the home and in the foreign department. The inguinal glands alone are attacked, the exciting cause being a sprain or an abrasion on the toe, but there may be no appreciable cause. The glands may or may not suppurate. The constitutional condition is usually low. In seven years the yearly average was 733 cases among 56,000 persons, or about 13 per 1000. These cases are reported with detailed symptoms.

TREATMENT.

I was taught some ten or twelve years ago, and that teaching was by some of the best genito-urinary surgeons at home and abroad, to cauterize the penile sore by pure carbolic or nitric acid, and then dust on iodoform if the sufferer was a charity patient, or if a private one boric acid and calomel, and encase the organ in a bichlorid dressing. This manner of procedure was invariably followed by buboes. Martin[18] says cauterization of the chancroid is the safest routine treatment, and for this purpose he advises zinc chlorid, caustic potash, bromin, iodin, nitrate of silver, and the actual cautery. By far the best means is the actual cautery, either the glowing iron, the Paquelin apparatus, or the galvanic cautery.

Munn[20] advocates in cases of concealed chancroids with phimosis, incision of the dorsum of the prepuce, curetting of the infected sore and the soft mushy adjacent tissues, followed by circumcision. Out of 21 cases thus treated, all but two were successful. Thorough antiseptic precautions were practised in all cases. In regard to reinfection, he makes the following statement: "Theoretically, it might seem that infected lymphatics would reinfect deep tissues after the most thorough curettage, but this has not occurred, although in a number of instances the inguinal lymphatic glands were so enlarged as to require excision at the same time as the circumcision."

If I have the good fortune to see the chancroid in the first 48 hours or during the first week, providing the lesion has not involved much of the surrounding tissue and is superficial rather than deep, I pro-

ceed as follows: The patient is put under ether, the surrounding parts are shaved, then washed with green soap and water, then irrigated thoroughly with bichlorid, 1–2000, the lesion is thoroughly cauterized with the Paquelin cautery and then dressed with glutol-Schleich and moist bichlorid gauze, 1–1000. If the latter is put on properly it will not come off. My practice is to leave the dressing on from 5 to 7 days. If it is necessary to redress the wound the same steps are repeated with the exception of the cauterization. My results show a cure in from 7 to 12 days. Fifteen cases thus treated give an average cure in 12 days, without buboes. If the lesion has involved much tissue, the above steps are followed out with the exception of using the cautery. A sharp curette is employed. The average cure in 10 cases has been from 14 to 17 days. No complication of bubo was observed. In those cases complicated by a slight inguinal enlargement it is my practice to apply some unguentum hydrargyri (U. S. P.) and a pad consisting of a sufficient number of layers of gauze to make it one-half an inch in thickness, 6 inches in length, and 3 in width, which is held in place by a tight spica. In these cases the inguinal enlargement disappears as the chancroid heals.

In cases of chancrous phimosis I believe the treatment advanced by Munn is the most rational procedure yet proposed. My experience with this method embraces only eight cases, all of which responded promptly without reinfection or complication.

The treatment of buboes is generally divided into the following methods: (1) External applications. (2) Hypodermic injections of various medicinal agents into the gland. (3) Incision. (4) Excision.

To abort buboes in their first stage by the external application of drugs is in the majority of cases hopeless. Tincture of iodin, belladonna ointment or ichthyol (10 per cent.), when applied to a bubo as a complication of a chancroid, is simply a waste of time and does more harm than good. In some cases of gonorrheal and non-venereal buboes I have seen the application of belladonna ointment, with the gauze pad and a tight spica, yield some very good results, but I believe that these were obtained more through the effects of the spica than from the ointment.

The treatment of buboes by hypodermic injections of various antiseptic solutions has been proposed as a method of absorbing them. M. K. Taylor[21] advocated the use of 10 grains to the ounce of carbolic acid, 10 to 40 minims of this solution being injected into the bubo. I gave it a trial in six cases of buboes from chancroids and it was a failure in each instance.

Welander[8] advises the use of a 1-per-cent. solution of benzoate of mercury to abort buboes and reports good success. Out of 15 cases thus treated by the writer 2 were successful, and in 13 cases it failed. In each instance there was considerable pain, and in 1 case the reaction was so marked that the patient was confined to his bed for three days with a fever that ranged from 100° to 103° F., and finally the bubo had to be incised. The treatment of suppurating buboes by incision as soon as fluctuation is observed is in the writer's opinion by far the best practice in these cases.

Helm[23] was the first to devise the treatment of buboes by incision and the application of iodoform blown into the cavity. This method with the modification of using iodoform ointment in the cavity was very carefully discussed in a paper by Fountain,[22] but it was reserved for Hayden[24] to modify and demonstrate this form of treatment, and institute a method which to-day gives better results than any other method yet devised. In 25 cases treated by Hayden's method the average duration in which the patient was under treatment was 18 days. The shortest was 9 days and the longest 24 days.

In 40 cases treated by the writer's method, which is nearly the same as Hayden's, with one or two exceptions, I obtained the following results: 28 patients were cured in 6 days, 7 in 9 days, 3 in 12 days, and 2 in 18 days. The shortest duration was 6 days, and the longest 18 days, the average being about 11 days. The different steps are as follows: The parts are shaved and scrubbed with hot water and green soap, then washed with bichlorid, 1–1000; a few drops of a 4-per-cent. solution of cocain are then injected under the skin at the most dependent point of the bubo, and it is again washed with bichlorid, 1–1000. The incision is made at the selected point with an ordinary sharp-pointed bistoury carried well into the bubo, and all the pus is expressed by firm pressure. The cavity is then irrigated with pure peroxid of hydrogen. This is continued until the fluid returns clear. This is followed by irrigation with a warm solution (100° F.) of bichlorid, 1–3000, for 2 or 3 minutes. The cavity is filled with glutol-Schleich, forced into it by a powder blower of sufficient size to allow the glutol to pass through it, and glutol is sprinkled over the external wound. A gauze pad squeezed out in 1–3000 bichlorid is placed over the wound, and a tight spica bandage is placed over all.

It is my practice not to remove the bandage for 6 days unless there is staining from the discharge or the bandage has slipped. It is best for the patient

to remain on his back for the first 24 hours. The scar left from the incision is small. The glutol in my hands has given me better results than has 10-per-cent. iodoform-vaselin, and a great factor to be considered, especially among private patients is the disagreeable odor of iodoform, to which one and all most emphatically object, as they believe it is a trade-mark of their trouble.

The excision of buboes has for its champion Watson[25] who has very carefully laid down the rules and steps of the operation, and reports an amount of success that hardly seems possible. From 20 unselected cases, he gets union by first intention in 10 cases. Taylor[12] is also a mild advocate of this method. I am of the opinion that the operation is unnecessary. Dr. Coley of New York informs me that he has observed hernia, as a result of this operation, in a number of instances in his service at the Hospital for Ruptured and Crippled. I have seen in the past few weeks a man who was rejected from the United States service because of similar scars. I have practised this operation four times. A cure was attained in all cases, but two required 28 days, one 22, and the other 26 days.

The buboes of syphilis respond promptly to the specific treatment. They seldom suppurate. The buboes of gonorrhea can be aborted by the application of some mild ointment with pressure applied in the form of a spica.

The buboes of non-venereal or traumatic origin respond well to the treatment of pressure by a tight spica with some mild ointment applied over the bubo. It may be necessary in some cases to place the patient on some appropriate internal medication. One must be governed by the individual requirement in each case. It is rare for these buboes to suppurate.

Gaither[26] advoçates a method of absorbing buboes by means of a pressure bandage, which is applied as follows: "A piece of cotton as large as the fist is folded in on itself again and again until it has the shape of the bubo, and when placed on it does not completely cover it. This is carefully adjusted and a wad of tightly compressed cotton as large as a cocoanut placed over it. Small pieces of cotton are also used on the inner and outer surfaces of the thigh to prevent chafing. A very tight spica bandage is then put on. This bandage is put on regardless of the age of the bubo, and a satisfactory result was obtained in more than 85 per cent. of the cases."

The conclusions which the writer wishes to convey, are: First, he believes that with proper care of the sore on the penis the complication known as bubo may be aborted; second, that there is but one method to treat suppurating buboes successfully and that is by early incision of the tumor and antiseptic treatment. The operation becomes of importance only after the incision when careless after-treatment makes the percentage of uncured cases high.

CHOLELITHIASIS; WITH A REPORT OF SOME OPERATIVE CASES OF DR. CHARLES M'BURNEY.

BY HOWARD D. COLLINS, M.D.,
OF NEW YORK;
ASSISTANT TO THE ATTENDING SURGEON OF ROOSEVELT HOSPITAL; ASSISTANT DEMONSTRATOR OF ANATOMY IN THE COLLEGE OF PHYSICIANS AND SURGEONS.

ESTIMATES have been made that ten per cent. of all persons have gall-stones at some period of their lives. It is also stated that only about a quarter of these persons suffer from the presence of the calculi. It is impossible to prove the accuracy of these figures, but we do know that autopsies are frequently made on individuals in whose gall-bladders a number of stones exist, and yet the calculi have given rise to no trouble during life. Why one individual should be made to suffer the pain and misery which form the striking symptoms of the disease while another, with the same pathological conditions, can journey through life entirely unconscious of the sufferings he has escaped is difficult to answer. The causes of gall-stones undoubtedly depend on two main pathological changes: an inflamed condition of the mucous membrane lining the bile passages and an altered condition of the bile itself, although there are other contributory factors of secondary importance. The change in the mucous membrane of the ducts is an extension of a similar process from the lining of the intestines and stomach, having as its etiology a gastroduodenitis of a mild chronic type brought on by abuse of the alimentary tract. This alteration in the mucous membrane favors the deposit of the cholestrin, inspissated bile, and other bile elements which go to make up the substance of the calculi.

The change in the composition of bile that favors the formation of calculi is a decrease of bile salts and a diminution of the watery elements. Biliary calculi are formed in the bile radicles of the liver, or more commonly in the gall-bladder. As to shape and appearance, one may classify the stones into three general forms: The first and perhaps least common are large, smooth, rounded, or ovoid masses about the consistency of dry putty and are easily broken up. They are not infrequently half an inch in diameter. The second type consists of small, rounded masses covered with little sharp spicules. The stones are hard, jet black, and about one-quarter of an inch in diameter. The third and most common form is the familiar, smooth-facetted brown stone, with a great range of size, varying from tiny particles to that of a large hazelnut. In addition to the calculi simple inspissated bile may give rise to the symptoms of cholelithiasis.

After the calculus is formed at its site of origin, either in the gall-bladder or in the liver, its subsequent history may be as follows: The calculus makes no attempt to escape, but remains quiescent, not giving rise to symptoms; or else the stone makes one or more attempts to pass out of the gall-bladder, but finding the cystic duct too small, falls back into the gall-bladder only to renew the attempt later. Still another type is that in which the stone leaves its site of origin, passes into the bile-ducts (either the cystic or hepatic), hence into the common duct, and finally escapes into the duodenum. The cases in which the worst class of symptoms arise are those in which there is an attempted passage of a stone, but the final escape into the intestine fails and the calculus remains lodged in the common duct.

The symptoms of these several conditions are but logical deductions of the various causes. When the stone remains quiescent in the gall-bladder or liver there are no symptoms; if the calculus attempts to leave the gall-bladder there is pain, due to the partial distention of the cystic duct, owing to the attempts of the stone to engage, and also pain from the distention of the gall-bladder with mucus, with cessation of pain when the stone slips back into the gall-bladder and the mucus has a chance to escape. The complete passage of a calculus, unless very small, produces the well-known symptoms of biliary colic. Intense agonizing pain in the region of the gall-bladder, radiating to the back and epigastrium; the sudden cessation of the pain, with the development of jaundice in a day or two, are the main symptoms. The jaundice is due to the obstruction of the common bile-duct by the swollen mucous membrane, produced by the irritation of the stone in its passage.

The most interesting class from the standpoint of the surgeon is that in which the gall-stone, having left its point of origin, attempts to pass into the intestine, but finding the ducts too small, is caught at some point in the lumen of the cystic, hepatic, or common bile-duct and is unable to advance or to retreat because the swollen mucous membrane has diminished the caliber of the duct. Here the stone remains, more or less occluding the duct. The bile, if the stone is in the hepatic or common duct, banks up behind and around the stone until the duct is sufficiently distended to allow the bile to pass the obstruction and thus escape into the gut. This condition repeats itself until a permanently dilated area is formed in which the stone rocks back and forth like a shuttle in its groove, occasionally obstructing the passage of bile by becoming caught in the distal end of the tube and acting as a ball-valve whenever the stone attempts to escape.

The general symptoms of such a state of affairs

are, first, an attack of sharp, severe pain, coincident with the original excursion of the stone. The pain gradually subsides as the duct becomes stretched and accustomed to the pressure of the stone. There is also severe and prolonged jaundice with several exacerbations until the duct has become sufficiently enlarged to allow the bile to flow freely around the obstruction. When the dilatation of the duct is well established the patient returns more or less fully to a state of good health, but the presence of the stone in the duct is a source of subsequent attacks of pain and jaundice. If the stone has become lodged in the cystic duct the jaundice is absent, but the mechanical conditions are the same; the gall-bladder becoming distended with mucus causes much pain. The gall-bladder may empty itself by dilating the cystic duct, or a condition of empyema of the gall-bladder may supervene.

Not much skill is needed to make a diagnosis of gall-stones when the main symptoms are paroxysms of pain in the region of the gall-bladder radiating to the back and epigastrium, followed by jaundice, although one must bear in mind the possibilities of tumors pressing on the passages. The difficult cases to diagnose are those unaccompanied by jaundice. In such cases the pain is often referred to the epigastrium, begins with moderate severity, and may take two or three days to reach its climax (here the pain is caused by the gall-bladder being distended with mucus). The pain ceases when the tension is relieved. Many of these patients are treated for gastric neuralgia, gastric gout, indigestion, dyspepsia, etc.

The treatment by medical means is directed toward restoring the normal state of the mucous membrane and rendering the bile more fluid. The treatment is mainly prophylactic. The plans often suggested for dissolving stones already formed are absurd, but undoubtedly medicinal treatment is of great service in favoring the passage and escape of calculi already formed. Dr. Delafield uses olive oil empirically, in pint doses, for this purpose, and has had excellent results. For the removal of stones too large to pass through the channels of exit, and which call for interference on account of prolonged jaundice, empyema of the gall-bladder, abscess of the liver, or continued attacks of severe pain, surgery is the only relief. If it could be positively determined that the lesions were confined to the gall-bladder, either as a gall-bladder overdistended with mucus, pus, or calculi, the operation could be made comparatively simple. The plan in such a case would be as follows: A short vertical incision should be made through the abdominal wall just to the inner side of the outer margin of the rectus muscle over the fundus of the gall-bladder. The gall-bladder should then be drawn forward and stitched to the edge of the wound. The next day, after sufficient time has elapsed to shut off the peritoneal cavity by an agglutinating peritonitis, the gall-bladder should be opened and the contents evacuated. After several days of free drainage the gall-bladder and abdominal wound should be allowed to heal by granulation Such a procedure would be rapid, safe, and sure. On the other hand it is almost impossible to determine, through a small incision, whether the lesion is confined solely to the gall-bladder or whether some additional trouble is present in the liver or ducts. This point must be positively determined before it is justifiable to limit the operation merely to opening the gall-bladder. To make a careful examination of all the bile passages a generous incision is needed.

In determining the best forms of incision the fact must be borne in mind that, other conditions being equal, the subsequent tone and vigor of muscular tissue after operation depends on the number of nerves supplying those muscles which have been cut. It is also perfectly well established that a muscle split in the direction of its fibers presents a stronger healed surface than those in which the fibers have been cut across. A review of the course of the dorsal nerves which supply the rectus and other abdominal muscles will aid in determining the line of incision. The lower dorsal nerves emerge from under cover of the ribs, pass obliquely downward, forward, and inward until they reach the margin of the rectus. On reaching the outer margin of the rectus the nerves divide into two branches, the upper branch passing inward and slightly upward and the lower inward and slightly downward. The course of the nerves can be very accurately outlined by mapping out certain lines on the abdomen. For this plan I am indebted to Dr. George E. Brewer. The plan is as follows: From a point one-half inch below the tip of the last rib draw a line to the spine of the pubes of the opposite side. This line, or rather as much of it as extends from the point of origin to the outer margin of the rectus muscle, very accurately overlies the twelfth dorsal nerve as it courses along under cover of the internal oblique. On reaching the border of the rectus the nerve splits into its two branches as described above. A similar line drawn from a point one-half an inch above the tip of the twelfth rib to the middle of Poupart's ligament on the opposite side marks the eleventh nerve. A line starting one-half inch in front of and above the tip of the eleventh rib and extending to the anterior-superior spine of the ilium of the opposite side traces the course of the tenth nerve. The eighth nerve

runs just below the inferior margin of the eighth rib, passes forward and upward to the ensiform cartilage, following closely the curve of the eighth costal cartilage through the entire distance. The nerve never lies more than half an inch below the inferior margin of the eighth rib or cartilage. The ninth nerve lies between the ninth and tenth ribs. It leaves the line of the ninth rib at the osteochondral junction and passes forward, downward, and inward to the margin of the rectus muscle. There are no suitable landmarks from which to find the approach of the ninth nerve to the edge of the rectus. It is sufficiently accurate to describe the ninth nerve as splitting up into its two branches at the edge of the rectus at a point midway between the entrance of the eighth and tenth nerves into the muscle.

Having mapped out the nerves an incision should be made which will destroy as few nerves as possible and at the same time give enough room for free exploration and operation. The best incision extends from about half an inch below the free border of the costal cartilages to a point two or three inches above the umbilicus. It passes just within the outer margin of the right rectus muscle. The wound only destroys one nerve, the ninth, and divides the muscle in a longitudinal direction. It also provides enough room for exploration and operation. Another point of entrance which offers the advantage of giving far more room without destroying any more nerves (the ninth being destroyed in either case) is a curved incision parallel to the free border of the costal cartilages and about one inch below them. The incision starts just below and to the outer side of the ensiform cartilage and may be made to extend as far posteriorly as the point of emergence of the tenth nerve. A serious objection may be urged against this second incision, for, although a far greater field is exposed, nevertheless, the muscle fibers of the rectus, external oblique and transversalis are divided at nearly right angles to their long axes. Even after primary union a cut muscle is not so strong as a split muscle.

Having freely exposed the gall-bladder and subhepatic region by means of either of these incisions the bile-ducts should be carefully examined with the finger to detect any impacted calculi that may be present. It is quite possible that a stone lightly lodged in the ducts may be pushed by manipulations into the intestine either by accident or design. But the greatest care and gentleness must be observed in the attempt to force a stone onward as it is not a difficult matter to seriously injure or even rupture the ducts by attempting to crowd through them a stone larger than the caliber of the ducts will admit. After locating the calculi in either the gall-bladder or the ducts the question of the best method of removal must be decided. If in the gall-bladder, the calculi are removed through an incision in the fundus of the gall-bladder after the latter has been stitched to the abdominal wound. The entire abdominal wound may then be closed by suture except the small portion surrounding the fundus of the gall-bladder. On the other hand, if the calculus be impacted in one of the ducts, the duct is incised and the stone removed and subsequently the wound in the duct is sutured, but only a part of the abdominal wound can be closed, as leakage from the sutured duct must be guarded against by packing.

The anatomical position of the lower part of the common duct coursing behind and under cover of the duodenum is such as to render the exposure of the duct by dissection entirely impracticable. Hence, it is impossible to extract a calculus impacted low down in the common duct by incising the duct at the point of obstruction. To obviate this difficulty Dr. McBurney has devised the plan of opening the intestine and withdrawing the obstructing calculus by means of forceps introduced through the intestinal orifice of the common bile-duct. An additional value of this method is that it permits a greater closure of the abdominal wound than would be safe when the bile-ducts have been incised, for although the ducts have been closed by suture, the risk of leakage is great and must be guarded against by generous packing. The dilatation of the orifice of the duct is also a probable advantage.

The operative procedure is as follows: The abdomen is opened by either the vertical incision or the curved one along the margin of the costal cartilages. Any adhesions that can be broken down with safety are destroyed. An incision one inch long longitudinal to the long axis of the gut is made in the anterior wall of the duodenum, about an inch below the beginning of the descending portion. With the finger the cavity of the descending duodenum is carefully explored until the papilla marking the conjoined orifice of the common bile-duct and pancreatic duct is felt. This papilla is situated at the junction of the inner and posterior walls of the duodenum and about an inch below a crescentic fold of mucous membrane which marks the angle of junction between the ascending and descending portions of the duodenum. The papilla is then drawn into plain view, the orifice identified, and a probe passed into the common duct.

Having established the entrance into the bile-duct a pair of toothed forceps is introduced along the interior of the duct as far as the obstructing calculus, which is then grasped with the forceps and withdrawn. The introduction of the forceps and the re-

moval of the stone markedly dilate the normally narrow opening of the common bile-duct. The dilatation of the orifice is of probable value in permitting the easy escape of the inspissated bile or small calculi that may have escaped observation. The intestinal wound is now closed by an ordinary double row of sutures and the abdominal wound closed, or a drainage-tube may be left leading down to the suture line in the intestine. The tube is only left in place forty-eight hours, after which time the wound may be fully closed with secondary sutures.

One of the most annoying sequelæ of cholecystostomy is the long time the biliary fistula remains patent, in some instances never closing without a second operation. In the more recent cases of patients operated upon at the Roosevelt Hospital Dr. McBurney has employed a modification in technic which has markedly hastened the closure of the fistula. The ordinary procedure has been to suture the edge of the incision in the fundus of the gall-bladder to the opening left in the abdominal wall. A rubber tube or gauze drain is then put into the gall-bladder. Dr. McBurney's plan is to suture the circumference of the gall-bladder about one-half an inch below the fundus to the edges of the abdominal opening. A purse-string suture is then passed around the gall-bladder between the opening in the fundus and the line of suture to the abdominal wall. The purse-string, of course, involves only the muscular and serous coats. The free edge of the incised fundus is now inverted with thumb forceps, a small rubber drainage-tube introduced, and the purse-string tightened so as to prevent a reversion of the inverted parts to their original position. Of course, the suture is not drawn tight enough to occlude the lumen of the rubber drain. The value of this method is apparent when, after several days, the drain is removed. The inverted flaps act as valves to partially prevent the leakage of bile, and, more especially, the serous surfaces are approximated, thus producing far more rapid closure than if one depended upon granulations.

In the following five cases only the gall-bladder was opened and drained by either a rubber tube or gauze: (1) The biliary fistula was patent and bile flowing freely at the end of one month. (2) Bile still flowing at end of six weeks. (3) The gall-bladder was found empty. Subsequent discharge of bile was very slight. Fistula closed in three weeks. (4) Many stones were being discharged and fistula did not close for two and one-half months. (5) Bile still discharging at end of two months. As opposed to this list attention is called to the rapid closure in cases in which the gall-bladder had been inverted. (*a*) Nine hundred and fifty-nine stones removed. The fundus was inverted. In ten days the fistula was closed. (*b*) Fundus inverted. No discharge of bile at the end of five days. (*c*) Practically no discharge at the end of eight days.

There have been five patients operated upon by the method of opening the duodenum and extracting the calculi through the opening of the common duct. The first operation was performed in December, 1896. The technic was the same as has already been described. After closing the gut a glass drainage-tube was left extending from the abdominal wound to the line of suture. The calculus was found to be half an inch long and three-eighths of an inch in diameter, lying in the lower part of the common duct. The patient died in three days. After death the intestinal wound was found closed and the bile passages normal. The intestines were enormously distended. No gross evidences of peritonitis.

A second patient was operated upon in June, 1897. Two large calculi were felt in the lower part of the common duct and were removed through the intestine. Several large calculi were removed from the gall-bladder through an opening in the fundus. There was also a large stone in the cystic duct, which was removed through the gall-bladder. The intestinal wound was sutured and a glass drain left in the abdominal wound leading to the line of suture. The fundus of the gall-bladder was inverted around a small rubber tube. At the end of two days the glass tube was removed, and at the end of five days the rubber tube also. There was no leakage after the tube was removed. At the end of one month the wounds were healed, but the patient had another attack of biliary colic with jaundice. The symptoms disappeared in a week and since then he has been in complete health. The secondary attack was doubtless due to the passage of some small calculi overlooked at the time of operation. There were two other instances of impacted calculi being removed through the intestine. The histories are not at hand, but the results were successful and the healing rapid.

The most recent case was that of a patient operated upon in April, 1898. A calculus of the size of a hazelnut was found impacted close to the intestinal orifice of the common duct. The intestine was incised. By placing the finger outside the lumen of the gut, but within the angle between the ascending and descending duodenum, the stone could be felt and pushed, together with the orifice of the bile-duct, into the incision in the gut. Then the orifice of the duct was peeled off from the calculus and the stone was removed. The gall-bladder seemed to be empty and was not opened. After closing the intestinal wound the entire abdominal wound was

closed by sutures. At the end of eight days the wounds were healed, the patient much improved, and there was every prospect of a complete and rapid recovery.

CLINICAL LECTURE.

FACIAL NEURALGIA.[1]

BY WM. L. RODMAN, M.D.,
OF PHILADELPHIA;
FORMERLY PROFESSOR OF SURGERY AND CLINICAL SURGERY IN THE KENTUCKY SCHOOL OF MEDICINE; SURGEON TO THE STS. MARY AND ELIZABETH HOSPITAL; CONSULTING SURGEON TO THE LOUISVILLE CITY HOSPITAL.

THIS patient, Mr. B., aged forty-one years, was sent to us by Drs. Brown and Ishmael of Winchester, Ky. He has been troubled with a neuralgic condition of all the branches of the fifth nerve on the right side. The pain at first was thought by himself and his wife to be due to his teeth, and with that one idea in mind he applied to a dentist and had a number of teeth withdrawn; in fact, all the upper teeth on that side except the last molar. He says that the pain extends to the middle line; there is no pain on the left side at all; it comes down below the eye, up above the eye, and on the side of the head back as far as the filaments of the fifth nerve are distributed. This makes the case, then, one of neuralgia of the fifth nerve.

The history of the case would not seem to indicate that the trouble is of central origin. The patient has never had any specific disease, nor has he ever had any lesion that would lead one to think that there is any central trouble. He has recently suffered from various local complaints, but I will not speak of them as I cannot see that they have any bearing on the case and you might be misled thereby.

It will be noticed that the left side of his face twitches a great deal; that it is markedly choreic, though on this side he says there is no pain. The pain is confined entirely to the right side, and has existed almost continuously during the last fifteen months, whereas the choreic symptoms on the left side have lasted six or seven years. As a matter of course he has suffered greatly, and has taken everything in the materia medica in order to obtain relief, which has not been secured. He has been under the care of some of the most intelligent and up-to-date physicians in the State of Kentucky, and has had the benefit of everything that can be suggested in the way of medical treatment. Of course, medicinal agents give him relief to a certain extent, but do not effect a cure, and his physicians, after having treated him for fifteen months, have come to the conclusion that nothing but surgery offers promise of permanent relief.

The only kind of surgery suited to a case of this kind, or that would offer anything, would be intracranial section of the fifth nerve. Time and time again I have excised the supra-orbital and inferior orbital as well as other branches of the fifth nerve for relief of conditions of this kind, and while relief has been temporary, in no case in my own practice, or of which I have knowledge in the practice of my confréres, has the relief been at all permanent. The pain has always returned. Therefore we must offer something more than temporary relief, and if we operate upon this patient, as I think we shall, then it will be an intracranial neurectomy of the fifth nerve. The best operation for reaching the fifth nerve is one which was devised at the same time and independently of each other by Hartley of New York, and Krause, a German; therefore, it is generally spoken of in this country as the Hartley-Krause operation. The head having been well shaved and rendered thoroughly aseptic, an omega-shaped incision is made down to the bone. The temporal or other vessels that bleed are caught up, the flap turned down, and with a chisel a free cut is made into the bone all around to the same extent as the flap of the soft parts. In turn the external table and the diploe are cut through, and with retractors the flap is lifted up, the bone, muscles, and periosteum being turned back so as to allow ample room. The brain is then lifted up and the two main branches of the fifth nerve, which come in here at the foramen ovale and foramen rotundum are easily found. The two branches can easily be traced back to the Gasserian ganglion, which is located in the apex of the petrous portion of the temporal bone. These two branches, the superior and inferior maxillary, pass out from the lower two-thirds of the Gasserian ganglion. It is best, as a rule, not to interfere with the first division of the fifth nerve, because it is the ophthalmic branch which goes to the eye, and very serious conjunctivitis and panophthalmitis may ensue if this branch of the nerve is cut. For that reason it is also best not to interfere with the upper third of the ganglion of Gasser, for if it is all taken out the ophthalmic branch will be affected. Even though I shall aim not to injure the ophthalmic branch, I may do so during the operation. I shall sew his eyelids together before the operation and keep them sewn together for a week afterward, so as to keep out the light, and try to prevent any inflammation about the eye.

There are dangers in this operation, as a matter of course. It is not an easy operation in the first place, neither is it one devoid of danger. It is to be expected that hemorrhage is a feature of the operation for the reason that the temporal artery is cut when the soft parts are divided. When the bone is cut through and then fractured and the flap overturned, the middle meningeal artery will frequently be ruptured. It depends upon whether the artery runs through the foramen or through the groove at the anterior inferior angle of the bone. Sometimes it is in the groove, sometimes in the foramen; if it is in the groove it will not be ruptured; if in the foramen it likely will be. It is not a particularly grave accident because the wound is an open one, and the meningeal artery can easily be grasped and tied. The temporosphenoidal lobe is the one to be raised. Underneath the base of this lobe can be seen the second and third branches of the nerve, one going to the foramen ovale, the other to the foramen rotundum, and during this step of the operation it is better for the surgeon to have a good mirror attached to his forehead in order that a strong

[1] A Clinical Lecture delivered at the Hospital of the Kentucky School of Medicine.

light may be thrown on the field of operation. As the brain is lifted up and the surgeon cuts down upon these branches he necessarily divides some blood-vessels, but if the operation is performed carefully hemorrhage, as a rule, is not great, though in many cases it has been so profuse as to necessitate immediate packing with gauze, the gauze being left *in situ* two, three, or four days, the operation thus being completed in two stages. So great a surgeon as W. W. Keen of Jefferson College, Philadelphia, has reported nine cases of this operation, and if I mistake not, in four or five of them he was compelled to complete the operation in this way. In one case he packed in an enormous quantity of gauze before hemorrhage was controlled. Many other operators, Hartley of New York, Tiffany of Baltimore, Gerster, McBurney, and others, have completed the operation at one sitting, and do not speak of hemorrhage as being such a marked feature of the operation. Still, one should be prepared for considerable hemorrhage, although the operation should be completed at one sitting if possible.

The brain is lifted up and the two branches of the fifth nerve followed back to the ganglion of Gasser; then the two branches between the foramen in front and ganglion behind are cut out. In removing the Gasserian ganglion it is necessary to be very careful not to sever the large blood-vessels in its immediate vicinity. The entire flap is then turned back into position, and a drainage-tube is inserted and allowed to remain in place for forty-eight hours. The wound usually heals without trouble.

The dangers of the operation are principally those from shock, and it can be understood that shock is great. The next danger is the occurrence of sepsis; and the next that an abscess may occur perhaps two, three, four, five, or even six weeks, or even later, after the operation. I believe all these dangers have been exaggerated. Tiffany of Baltimore, a most excellent surgeon, reviewed all the published reports of cases up to the time of delivering his presidential address before the Southern Surgical and Gynecological Society, which met in Washington last November. He wrote to every surgeon in the country to know if he had performed the operation, and as a result of his inquiries he reported 108 cases, many of the patients having been operated upon by himself, but more by Keen than any one else. The mortality following the operation was shown to be about twenty-two per cent., and I have already explained to this patient and his friends that his chances of dying are about one in five. I was perfectly candid with him, and told him what I have just stated to you. I have told him, furthermore, that the less serious operation of excising the inferior and supra-orbital nerves might give him relief, but that I have never seen it occur, although if he wished to have it tried first I was willing to do it.

A great many other operations have been suggested in the past. For instance, Meckel's ganglion may be removed. This was first done in this country, if not the first time in the world, by the elder Pancoast, at that time professor of surgery in Jefferson Medical College, one of the greatest surgeons the world has ever known. The skill and dexterity with which he operated was marvelous. I saw him operate when he was past eighty years of age; he was in his dotage; he could not call anything by its right name, although he had taught anatomy for forty years. He came into the clinic one Saturday morning arrayed in a full-dress suit (he always came before the class in this dress), and his son, with a great deal of manner, characteristic of the family, said to his father: "Will not the distinguished Emeritus Professor of Surgery operate upon this patient?" The old gentleman said he would, and a patient was brought in with an enormous fatty tumor between the scapulæ. I never saw such a brilliant operation in my life. He made the incision with one stroke of the knife, and then with his fingers simply scooped the tumor out.

As I have said, he was the first to remove Meckel's ganglion, and one can readily understand the dangers attending such an operation at that period. Since then other, and I believe better, operations have been devised for the relief of the condition before us. Rose of England devised one in which he goes in from the outside down to the fossa, and resects the ganglion and process, penetrating to the superior maxillary fossa, but I think the best operation is the one of Hartley, the credit for which he is undoubtedly entitled, because he published the report of his case and showed the patient to the Surgical Society of New York before Krause had performed his operation or published a report of it, so we unquestionably should call it the Hartley operation. I probably shall perform the operation upon this patient one week from to-day, or it may be sooner.

The question may come up in your minds, Why perform an operation, seemingly so very severe, in which the chances of the patient's dying are one in five, for facial neuralgia? Is it not too bold? Is it not in a measure unjustifiable? I have never myself suffered from facial neuralgia, but from reports received from patients who have I believe I would rather submit to any operation rather than suffer the pain of the disease, and it may be said that these patients practically never get well under medicinal treatment. If they are relieved temporarily it is only a question of time before they have another attack. That has been the history in the patient before us, and he says life is not worth living in his present condition, that he is becoming desperate from the constant pain, and is prepared to undergo anything which promises relief. Therefore, knowing how much he suffers now, I think we are justified in performing the operation I have outlined to you. Statistics show that the operation almost invariably cures these patients. As a matter of course, if the operative technic is imperfect, if part of the ganglion or even one branch of the fifth nerve is left behind, either the second or third, then the trouble may recur in the area to which that branch is distributed, but a complete and perfect operation almost necessarily promises immunity from neuralgia in that special locality for the balance of the patient's life. This man is a favorable subject, and should recover after the operation. He is only forty-one years of age, which is another good feature. Most of the cases reviewed by Tiffany occurred

in older subjects, and his mortality was about twenty-two per cent. In younger subjects it naturally should be less.

CLINICAL MEMORANDUM.

TRAUMATIC CATARACT IN AN INFANT'S EYE FROM PRESSURE OF FORCEPS.

BY EDWARD S. PECK, M.D.,
OF NEW YORK.

THE case I am about to report seems to be of sufficient importance to be brought before this Section on account of its rarity.

Shortly before eight o'clock on the night of October 14, 1890, I was called in great haste to see a newborn child, and was told that its right eye had been forced out upon its cheek during an instrumental delivery. The mother, a primipara, twenty-one years of age, had been in labor seventy-two hours; extreme uterine inertia had occurred and under anesthesia forceps had been applied by her attending physician two hours previously. The forceps was applied high up, with the result that the right blade fell across the right eye of the child just under the inferior lid. The skin of the forehead was injured a little to the right of the median line, and the helix of the right ear was tightly compressed and turned back, but not torn. Careful examination of the eye showed a large subconjunctival hemorrhage, the whole inferior cul-de-sac of the conjunctiva being filled with blood, and the lower lid correspondingly swollen. The eyeball was softened and flattened from above downward, and was of a quadrilateral form. The cornea was steamy, the pupil larger than its fellow, and the pupillary field was seen to rapidly change from a dull-grayish reflex to a dense whitish body. Under atropin dilatation the opacity of the lens was seen to slowly increase until a soft cataract entirely filled the area of the lens. These changes in the lens occupied about twenty minutes. The sclerotic and corneal coats were not ruptured, but it was feared that a partial detachment of the retina had taken place.

The treatment consisted of instillations of a solution of 1–5000 bichlorid of mercury over the eyeball at regular intervals, the application of ice-cold cloths, and a drop of a solution of atropin sulphate, 1 grain to the ounce, every four hours. On the following day the conjunctival hemorrhage and swelling of the lid had nearly disappeared, so rapid are the absorptive properties of the lymphatics of an infant. A fully formed milky cataract filled the area of the pupil, ocular tension had increased, but the eyeball still retained its square form.

On the following day, forty hours after the injury, the eyeball had resumed its spherical shape, ocular tension was equal to that of its fellow, all lid-swelling was absent, but the cartaract retained its opacity, milky white color, and absence of nucleus. On the ninth day of the child's life the condition was as follows: The lids of the eye opened slitwise without aid, the pupil and cataract being readily seen. The corneal opacity still remained. On the thirty-third day both eyes opened equally well, the cornea had regained its clearness and reflex, the soft cataract still persisted, but perception of light was manifested by subjective tests.

The child was next seen at the age of 5½ months, at which time the following notes were taken: Pupil responsive to light and of same diameter as that of its fellow. Palpebral slit of same size as the other. Ophthalmoscope by the direct method shows a red reflex, and the retinal veins and arteries can be traced. A soft and diffuse cataract remains, the opaque spots showing themselves in flocs. The scar on the forehead is adherent to the frontal bone; the helix of the right ear is bent back.

The child was nursed by its mother and at no time showed signs of pain in the eye. When he was about two years of age the right eye began to show a slight divergent squint. The following was the condition when he was last examined by me, in May, 1898, at the age of seven years and seven months: Right eye—V=20/70+: with a 1.D. lens, V=20/50: reads Jaeger handtypes No. II. with a + 2.D. lens, the head being slightly turned toward the light. Left eye—V=20/12; Jaeger No. I. is easily read at 3 to 16 inches. Right eye has a divergent strabismus of 2½ lines. There is a probability of almost, if not entirely, perfect vision in this eye. Frontal scar is still present, but the integument is no longer adherent to the bone.

The case is interesting for the following reasons: In the first place it is the only case of the kind on record. *Schmidt's Jahrbücher*, the *Index Medicus*, and the "Catalogue of the Medical Library of the United States," fail to furnish a case similar as to the cause of trauma and clinical facts. Secondly, out of 3 carefully watched cases of evolution of cataract due to injury, this is the first I have seen occurring in so young a subject. Thirdly, a trauma severe enough to produce not only cataract but diminished ocular tension, with possibly detachment of the retina and blindness, is followed in a few years by cataract absorption, re-attachment of the retina, and exceedingly useful vision, due to the natural processes of repair and not to operation.

[1] Read in the Section on Pediatrics of the New York Academy of Medicine, November 10, 1898.

MEDICAL PROGRESS.

Unconscious Childbirth.—BALEY (*La Med. Mod.*, August 31, 1898) attended a primipara aged twenty-three years, who was in excellent health. After two hours of slight labor pains the os uteri had dilated to the size of a two-franc piece. Then the pains seemed to die out, and the doctor returned home. Two hours later he was hastily summoned, the patient having stated that the pains were returning. Having prepared his hand for an examination, his surprise may be imagined upon finding the child fully delivered and lying in a pool of amniotic fluid. It was not breathing, but a hot bath and spinal friction restored it to life. The mother was entirely ignorant of the fact that the child had been born. She had perceived the flow of water and a slight increase in the pain, but nothing else. The child weighed six and one-

half pounds, and its delivery had not even broken the skin of the perineum.

A Simple Method of Sterilizing Catgut.—ROBSON (*Lancet*, October 1, 1898) has been experimenting with the sterilization of catgut in fluids the boiling-point of which is higher than water. He found xylol to be the most satisfactory. Catgut boiled in this fluid is better than that boiled in alcohol, for it shrinks, and thus gains in strength and "bites" better when tied. The exact method adopted is the following: The catgut is wound *loosely* from end to end round an elongated glass reel. Several of these glass reels are then introduced into a metal cylinder, the cap of which screws on, and after more xylol than is sufficient to cover them has been poured in, the cap is adjusted. The whole is then put into boiling water in the sterilizer and allowed to remain along with the instruments for from twenty minutes to half an hour. After thus being sterilized, the reels, with the catgut which has shrunk around them, are removed *at once*, and kept in ether in five-per-cent. carbolic-acid solution or in methylated spirit, the latter being preferable, as any aqueous solution tends to cause catgut to swell. In this solution they may be kept on the reels till required. The xylol should be used but once, as a certain amount of decomposition takes place and the catgut will soften if heated in it a second time.

The Simplest Treatment of Umbilical Hernia in Children.—SCHLIEP (*Thera. Monatshefte*, September, 1898) regards an umbilical hernia in the first or second year of life as an almost physiological condition, so common is it. It usually disappears as soon as the child learns to express its desires by some other method than by crying. Experiments have shown that the stump of the umbilical cord is prevented from drying up by the string which is tied around it. It is far better not to tie the cord, but to touch the end of it with a three- or five-per-cent. solution of nitrate of silver. If this is done the cord will dry up in a day or two. If the cord has not fallen off by the third day, Schliep removes it except a very short stump, and dusts the part with powdered formalin gelatin. A bit of cotton soaked in salicylic collodion covers this. Some days later the fragment of the stump which remained comes away, and the granulating surface is touched with a stick of nitrate of silver.

Schliep proposes to use the power of compression of collodion in the treatment of hernia, and especially in the treatment of umbilical hernias of children.

Symptoms of Gastric Perforation.—AUFRAY (*Gaz. Hebdom. de Med. et de Chir.*, September 8, 1898) gives the following rules for the recognition of perforation of the stomach before operation. The pain is sudden, intense, exactly localized, and almost invariably constant. It is usually increased by the ingestion of liquids. This abdominal pain, like the thrust of a sword, is the best diagnostic sign. There will be also noticed an especial tension of the abdomen, a certain hardness with retraction of the abdominal walls, which, if present, cannot fail to point to the stomach as the seat of perforation. Other signs less constant are the intensity and rapidity of the collapse, the absence of vomiting, the fever. As soon as laparotomy is performed the escape of gas without odor, at least without fecal odor, the presence of partly digested food, intestinal adhesions increasing upward, ought all to indicate to the surgeon that he has to do with perforation of the stomach.

Sulphrenic Abscess Following Appendicitis.—SPILLMANN (*La Presse Med.*, September 7, 1898) mentions the occurrence of an abscess after an attack of appendicitis in a rather unusual situation. Abscesses in the pelvis behind the cecum or in the lumbar region are by no means uncommon. In the case referred to a boy aged sixteen years became very much fatigued by a long horseback ride, and suffered from an attack of appendicitis. One week later his abdomen was dilated, there was marked dyspnea with absence of vesicular murmur in the lower portion of the right chest. The patient died without operation two weeks later. At autopsy it was found that a pocket containing about two liters (quarts) of pus existed between the diaphragm and the liver. The appendix was gangrenous and perforated. A sinus led from its base to the pocket above referred to.

Thrombosis and Embolism after Childbirth.—SINGER (*Archiv für Gynakologie*, vol. xvi, p. 218) shows that thrombosis and embolism is an important complication of childbirth, and one which is often overlooked. He reports thirty-five instances of its occurrence. From a study of these cases the following conclusions are drawn:

1. Formation of the thrombus is preceded by an irregular rise in the pulse-rate. This rise is associated with the development of the thrombus, and the maximum is reached when the thrombus is completely formed or symptoms develop in the lungs.

2. The curve of the pulse is characteristic.

3. In a typical pulse-curve in thrombosis the pulse rises, while the temperature remains normal. It remains high until the development of edema or a palpable hard cord or symptoms referable to the lungs cause the temperature to rise. If in the next few hours or days the temperature falls the pulse still remains high for some days longer.

4. A variation from this type is found in those patients in whom other causes have produced high temperature before the development of thrombus.

5. In such cases the thrombus is apt to be an infected one, and the discharges of the patient should be carefully examined in order to ascertain the character of the infection.

6. Such examination will often reveal the presence of gonococci.

7. The good results from the treatment of thrombosis follow its early detection, hence it is of importance to note carefully the pulse-curve as well as that of the temperature.

8. Rest in bed is the most important part of the treatment. Above all things the patient must not be allowed to sit or stand up. The pulse is the absolute guide. The patient ought to be kept in bed at least three weeks after the pulse has become normal.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, NOVEMBER 26, 1898.

THE last echoes of election excitement have died out, the results are definitely known, and we have all settled down for better or worse to accept those results. Most of us, we feel sure, are heartily glad that it is over. An election of to-day is associated with so much that is irritating to the feelings of intelligent citizens that one is glad to be rid of the nuisance of it all for at least another year. Verily, the methods at present employed to influence voters, the partisan clap-trap speeches, the cheap advertising dodges, the persistent appeal to prejudice and party spirit rather than to reason, the public betting, and its ostentatious publication for the purpose of influencing the men who, being sporty themselves, do not want to vote on a losing side and wait the announcement of the final odds to decide their vote for them—all this is enough to offend the intelligent voter to the soul. It forms a most interesting commentary on that palladium of our liberties, universal suffrage.

But the intelligent citizen must not permit his interest in political affairs to wane because politics is corrupt and debased; that is but to allow the present state of affairs to continue and perpetuate itself. Every citizen, and most of all the intelligent one, owes it to himself to be interested as to how he shall be governed. The doctor above all, with the influence that he consciously or unconsciously exerts in the community around him, is bound to put aside his personal feelings of repulsion for certain party methods and use the influence he possesses for what he considers the cause of good, honest government. In the profession as it is at present largely constituted, its members men of liberal education, broadened by application to a calling that teaches them "to hold nothing human as of slight consideration," with interests awakened in every phase of humanity's development and feelings rendered acute by constant contact with human suffering, there should be no lurking place for the man who selfishly neglects his duties as a citizen.

Instead of taking the place that knowledge of human needs should give it in politics, the profession is scarcely a factor to be reckoned with at all in the political arena. As a consequence, when there comes the question of reform through legislative action on some point demanded by the public health or by professional interests, medical men are scarcely listened to in the matter, their well-known tendency to shirk personal political duties being a sufficient guarantee to the politicians, as a rule, that the neglect of their petitions will be followed by no political consequences. To follow the selfish policy of avoiding all trouble by letting politics severely alone is not compatible with the duty the medical man owes to himself, his profession, and to his government. Every physician should, on the contrary, be the center of a circle of political influence that makes for what is best in local and general government. To fail to be such is to fall short of the mission that has fallen to the profession of later years, that of making human life more livable and its environment better calculated to foster the proper evolution of the race. This is a mission the signs of whose fulfilment are all around us at the end of the Nineteenth Century, in the pregnant influence of medical men in psychological questions, in the problems of sociology, in all educational matters as well as in their more proper field, the care of public health.

THE result of the secondary elections for the Prussian legislature in Berlin have just been an-

nounced, and the Social Democrats (Radicals) have made large gains. Among the members reelected by the radicals is Professor Virchow, the pathologist, who, despite his advanced age, nearly seventy-eight, still retains his interest in governmental affairs. Ever since his investigation of the conditions existing among the poor people in Silesia during an epidemic of typhus that raged there some fifty years ago, he has been an uncompromising Social Democrat, an intense advocate of popular rights. His attitude in politics threatened at one time to interrupt his scientific career, and he was compelled to resign his position as prosector of anatomy at the Charité Hospital, Berlin. He received shortly after, however, a call to the professorship of pathologic anatomy at Wurzburg, and six years later came back to Berlin in triumph as Professor of Pathology. He could then afford to have political opinions, and though it has deprived him of decorations, titles, and honors which would have been heaped upon him, he has clung firmly to the principles he adopted in the enthusiastic philanthropy of his younger days. Ever since the advent of the present emperor it is said that it has been hinted to him that the title of excellenz would follow a modification of some of his radical political views. The hint missed its purpose.

Despite his years, Virchow is a most faithful attendant on the legislative sessions, is listened to with a great deal of attention, and his opinions on medical and scientific questions carry the greatest weight. Though his lectures at the Charité begin in summer at 7 A. M. and at 8 A. M. in winter, it is not an unusual thing for him to be at the legislative rooms for a night session or on committee work until midnight or later, and yet be ready for his work next day. He is a true type of the great medical scientist. His scientific work has never drawn him away from the great interests of humanity, but on the contrary the reputation and influence gained in science have been used to help on the solution of difficult social questions now so pressing everywhere.

THE course pursued by President Dwight of Yale University in proffering his resignation because he has reached the age of seventy has our hearty approval. He considers that men at seventy are, as a rule, unfitted for the manifold duties that devolve upon a university president. He is himself a striking proof of the fact that there are some notable exceptions to the rule, and that some of the septuagenarians have the vigor to properly apply the immense practical experience with which a long life has furnished them. It is from men like him, however, that the example of laying down the burden at the seventieth year comes with the best grace, and will have the most forceful effect in inviting imitation. Very, very few men are capable of fulfilling responsible university positions whether in administrative or teaching lines after this age has been reached. Too often men continue to occupy them to the serious detriment of the university, making the position of faculty and trustees in the matter a most difficult one. Every step then that tends to the establishment of the custom of voluntary retirement at seventy is a welcome one. American universities have not been so much hampered by difficulties in this matter as have educational institutions abroad, but it is only a question of time until they will be face to face with it, and then a tradition such as President Dwight's example inculcates would be a most precious heritage.

Meantime President Dwight's services are too valuable to be dispensed with, and now that the example of his action will have its force, we sincerely hope that the trustees of the university will succeed in their efforts to retain him as the guiding spirit of the institution or at least have the advantage of his counsel and cooperation until the bicentenary celebration of 1901.

May we join with the many sons of Yale in expressing our best wishes for many years of usefulness for the Patriarchal President, whose living words and far-seeing acts have done so much for a great university and for the cause of education in our country. *Ad Multos Annos!*

OUR London correspondent comments in last week's issue of the MEDICAL NEWS on a typically *fin-de-siècle* exposure that took place recently with regard to the sale of supposedly abortifacient remedies. Some one got hold of the names of the parties who had sent to a certain concern for "Lady Montrose's Miraculous Female Tabules," advertised as an infallible remedy for "delayed menstruation from any cause," etc. Typewritten let-

ters were sent purporting to be "official," announcing to each of the customers of the Montrose concern that legal proceedings had been commenced against them for "the fearful crime of preventing or attempting to prevent birth." Arrest was to follow unless the party would "promise under oath as before God," never, *never* to attempt the crime again and send the writer two guineas for the legal steps necessary to quash the proceedings. The bait took marvelously well in most cases, but before the swindler could land his fish the police, put on the track by some more strong-minded individuals, swooped down on his office. More than 600 letters were captured, each containing the two guineas demanded.

The whole affair is a startling commentary on the character of the advertisements that even respectable journals admit to their columns. Even so-called religious journals are not above it, and some of the confessedly guilty ones in this case admit having sent for the remedy because they saw it advertised in a religious journal.

Meantime, there is a feature of the case that the English medical journals do not touch upon. These letters of confession are in the hands of the authorities. Every one who sent the two guineas evidently confesses that her idea in taking the miraculous tabules was to commit what her correspondent designated as "the fearful crime of preventing or attempting to prevent birth."

This is a felony before the English law. Will the letters be used to prove this and the confessed criminals be brought to justice, or will the police compound a felony and permit the affair to drop out of sight? In other words, does the statute on the English statute-books in this matter legally mean anything or nothing? We are very much interested in knowing the final outcome of the case.

DESERTED CITIES OF THE FUTURE—BOMBAY AND MADRAS.

How serious a matter the present outbreak of bubonic plague in India is considered to be, may be gathered from the above expression which forms the title of the leading editorial in a recent number of the *Indian Medical Record*. Bombay has been in the death-grip of plague since August or September, 1896, and has now entered upon the third epidemic. It is estimated that 398,000 people fled from Bombay during the period beginning October, 1896, and ending February, 1897. Familiarity with the disease has bred among the remaining inhabitants a certain disregard for its dangers and so the exodus upon the outbreak of this last epidemic does not compare in extent with what occurred in the preceding years. It has, however, proven a serious drain upon the city's population. Moreover, the intervals between the epidemics have been so short that many of those who fled before have not dared to venture back.

Behind it all, as the editor of the *Indian Record* says, is the awful insanitary condition of the city. Despite the well-directed efforts of English sanitarians and the expenditure of immense sums of money, extending over a long period of years this condition of affairs has developed: the subsoil water of Bombay has been steadily rising at the rate of about eight inches each year. Eleven years ago it was twelve feet below the surface; this time last year it was only four. Two causes have contributed to this event; first, drainage originally insufficient, and second, the introduction of a plentiful water-supply without proper sewerage facilities for carrying it away. By being allowed to accumulate upon the surface of the ground and saturate the soil, an abundant supply of pure water instead of being an unmixed blessing has proved a veritable curse. The bankrupt condition of the treasury due to the long business stagnation gives no hope of prompt relief from this underground culture-bed of infection which must sooner or later destroy or drive out the last inhabitant.

SODIUM BICARBONATE BY INTRAVENOUS INJECTION AS A PREVENTIVE OF DIABETIC COMA.

OUR esteemed contemporary the *New York Medical Journal*, in a recent issue, gives the principal place in its editorial columns to an article bearing the above title. As the subject is not a new one we may be permitted a few additional comments upon it so as to round up its present status for the benefit of the busy practitioner.

The theory of treating the acid intoxication, supposed to be the cause of diabetic coma, by alkalin infusions into the circulation originated with Stadelmann in Naunyn's clinic at Strasburg, and was first put into practice by Naunyn himself. He seemed

at first to attain some measure of success, and on the strengh of his recommendation the method was thoroughly tried in most of the large European clinics but, almost without exception, unsuccessfully. It was then suggested by the Strasburg school—Naunyn, Minkowsky, Stadelmann—that it was not in the fully developed coma but in its preliminary stages, before the accumulation of acids in the blood and tissues became too great, that alkalin treatment would be serviceable. That was some years ago, but the results have not been encouraging. Eichhorst, in the fourth volume of his "Specielle Pathologie und Therapie," 1897, says: "Certainly, if these infusions have ever done any good in counteracting a supposed acid intoxication they have never been effective for any length of time." Professor Gerhardt, whose reaction is supposed (we say supposed because Van Noorden denies it any significance in the matter) to indicate the presence of the toxic acids in the urine which result from the toxic acidemia, has never seen the alkalin infusions do the slightest good. The subject has been one of special interest to him, yet as reported in our Berlin letter [MEDICAL NEWS, April 4, 1898] he did not think these infusions had ever lengthened life by an hour, or given a single additional moment of consciousness. That this decided opinion would not have been expressed unless the remedy had been tried in all stages of the coma and especially at the beginning of it, any one who knows Professor Gerhardt's thorough clinical methods and his large clinical material will never doubt for a moment.

Professor Van Noorden, in his book on diabetes, published this year, expresses his utter lack of confidence in the alkalin infusions for the relief of any symptoms due to the toxic acidemia. Finally, Professor Naunyn himself, confesses in his book on diabetes in the series, "Specielle Pathologie und Therapie" edited by Nothnagel, June, 1898, that the alkalin infusions have not had the success that the theory of their introduction promised. He even admits that any good effect they may have had was perhaps due to the "exciting influence of the infusion" and cites an old case of Hilton Fagge's in which an *acid* infusion had had precisely the effect claimed for these latter-day alkalin infusions when first introduced.

The *Journal's* editorial is founded on two cases of Lépine, one of which was surely known to Naunyn when he wrote, for Lépine's work in diabetes has for years been along similar lines to that of the Strasburg school, yet he attaches no importance to it. Naunyn himself evidently tried the alkalin infusions at all stages of the coma and has given them up. He now uses large doses, ½ ounce to 1½ ounces of bicarbonate of soda by the mouth or rectum, sometimes with good results. Lépine has added considerably to our knowledge of the functional pathology of diabetes, but has not been fortunate in the recommendation of methods of treatment. He was one of the very few clinicians in Europe, outside of Strasburg, who saw any good come from alkalin infusions given at the height of diabetic coma. His claim of benefit from pilocarpin as a pancreatic stimulant in diabetes was not confirmed by others. It would seem then that no great weight should be attached to his conclusions in the present instance.

ECHOES AND NEWS.

The Sternberg Hospital. — The Sternberg Hospital at Camp Thomas, Chickamauga Park, was closed November 14th. The twenty-eight patients in the hospital were sent to Fort Thomas, Ky., and the medical corps transferred to the hospital at Savannah.

Professor R. H. Crittenden of Yale College. — Professor R. H. Crittenden has been appointed to succeed Professor Geo. J. Brush, who has recently resigned his position as Director of the Sheffeld Scientific School, and accepted an appointment as Professor Emeritus.

A Woman Medical Inspector.—Dr. Mary H. Murray has been appointed by the New York Board of Health medical inspector of the twelve public schools in the third ward of the Borough of Queens, New York City. Dr. Murray is a graduate of the Woman's Medical College of the City of New York, and served as interne in the hospital and dispensary for one year. She is the first woman honored with an appointment on the staff of school inspectors.

Faculty Appointments at the New York Polyclinic.—Dr. Charles H. Chetwood has been promoted from the position of adjunct-professor to Professor of Genito-urinary Surgery. Dr. Chetwood has recently been appointed visiting-surgeon to Bellevue Hospital. Dr. Frederick Whiting has been appointed Professor of Otology, to fill the vacancy caused by the resignation of Professor Sheppard. Dr. Whiting is visiting-surgeon to the New York Eye and Ear Infirmary.

Health of Troops in the Philippines.—The number of cases of sickness reported from Manila for the week ending

November 12th was 1816 as against 1894 the previous week. Of these 124 were typhoid, 608 malaria, 95 dysentery, 184 diarrhea, other intestinal troubles 42, gastric fever 19, wounds and injuries 79, heat 3, smallpox 39, including 6 Spaniards; all other sicknesses 610. The deaths were: typhoid 1, meningitis 2, dysentery 1, purpura hemorrhagica 1, smallpox 1.

Some Observations During Human Cremation.—It has been found that fat people burn more easily than thin, and women who have died in childbirth are most easily cremated, while persons who have died of consumption require more time and more fuel than any other class of cases. These observations were made in Japan, where the fuel used is fire-wood, placed directly in contact with the body. On an average about seventy-five pounds of wood is required for each complete cremation.

A New Weekly Medical Journal.—The *Indian Medical Record*, which originally appeared as a monthly, has been issued for some years every two weeks, and now proposes, if its subscribers will substantially support it in the change, to become a weekly. India has so far had no weekly medical journal; there would seem to be a field for this venture. The *Indian Medical Record* is thoroughly representative of what is best in medicine in the Far East. It deserves the success that its present proposal indicates.

Columbia Medical Students Forbidden to Smoke in the College Buildings.—President Low of the Columbia University has issued an order approved in a meeting of the Faculty of the College of Physicians and Surgeons, prohibiting smoking or spitting about the corridors or in the rooms of the buildings, except in the retiring-room and a designated part of the dissecting-room. The majority of men who smoke expectorate, and as this is now regarded not only as a filthy habit but as one which encourages the spread of disease, the new order will doubtless work a favorable reform in the habits of the medical students.

Antivivisection and Congress.—The scientific societies of Washington have recently held a joint meeting and passed resolutions calling the attention of scientists and the medical profession to the fact that a meeting of the American Humane Society will be held in Washington during December next for the purpose of reviving interest in the Antivivisection Bill now pending in the United States Senate, and urging upon the individual members of the medical profession the importance of personal letters being sent by them to their respective senators and representatives protesting against the bill.

The Health of the Army at Honolulu. — The conflict of authority between the local Board of Health and the Army officers on account of the insanitary condition of the camps has continued, the city authorities threatening to quarantine against the camps unless their condition was corrected. Fortunately, the camps were abandoned to time to prevent serious trouble. General King, who was ordered to conduct his troops from Honolulu to Manila placed them on shipboard but decided to wait three days before starting out, fearing an epidemic might arise during his voyage and compel his return. Later accounts announced that several cases of typhoid fever had occurred on board the ship, and that she had been placed in quarantine.

A Microbe-Proof House at Yokohama.—An eminent German bacteriologist has recently erected at Yokohama a microbe-proof house, built of glass blocks. There are no window sashes and the doors, when closed, are air-tight. The air-supply is forced into the room through a pipe and filtered through cotton wool to cleanse it of bacteria. To insure further sterilization the air is driven against a glycerine-coated plate of glass, which captures all the microbes the wool spares. The few microbes brought into the house in the clothes of visitors soon die in the warm sunlight with which the house is flooded. This affords a constant sunbath during clear days, and is a valuable suggestion to those personally interested in the sanitarian treatment of phthisis.

A Doctor Prosecuted.—The President of the New York Board of Health has preferred charges against a local physician for failure to report a case of diphtheria until after the death of the patient, and requested the corporation counsel to begin suit for $50 damages provided for in the Code. It is also alleged that in the doctor's death certificate the fatal result was ascribed to heart failure following undue exertion, although his letter incidentally stated that his patient had been ill with diphtheria from which he had recovered five days previous. The considerate and just treatment accorded by the Board of Health to cases of contagious diseases should put at rest any fear on the part of the attending physician regarding the consequences of proper notification, and be an incentive to prompt and ingenuous action in accordance with the requirements.

Ablation of the Spleen.—Jonesco of Bucharest read October 25th, before the Paris Academy of Medicine, a paper in which he reported twenty-nine cases of ablation of the spleen, from which he drew the following conclusions: The good results obtained by the ablation of the spleen of patients suffering from malaria confirm the opinion of Laveran, namely, that the spleen instead of being an organ of protection against malaria, is the receptacle of the hematozoa, from which the hematozoa are thrown into the blood. Therefore, to amputate the spleen is to remove the principal seat, if not the only one, of chronic malaria, and cure that disease. Consequently, the removal of the spleen must be performed as early as possible to prevent the formation of adhesions and cachexia, which would make the operation more serious, if not impossible. Leucocythemia in these cases is the only contraindication of the operation.

The Sixth International Otological Congress.—The Sixth International Otological Congress will be held in London, August 8, 9, 10, 11, and 12, 1899. President, Dr. Urban Pritchard, Professor of Otology at King's College, London. The meetings will, by permission, be held at the Examination Hall of the Royal Colleges of Physicians

and Surgeons, Victoria Embankment. The subject chosen for special discussion is "Indications for Opening the Mastoid in Chronic Suppurative Otitis Media." A large and influental British organization committee has been formed, the treasurer being Mr. A. E. Cumberbach, 80 Portland Place, London, W., and the honorary secretary, Mr. Cresswell Baber, 46 Brunswick Square, Brighton. The International Otological Congress, which assembles every four years, met last in Florence, where a very successful gathering was held under the presidency of Professor Grazzi.

Mt. Sinai Hospital.—Since 1872 the Mt. Sinai Hospital, New York, has occupied its present quarters at Sixty-sixth Street and Lexington Avenue. For more than ten years the present structure has proven inadequate to the demands made upon it, and a year ago the directors of the hospital decided to build a new and more modern structure. A site was purchased on Fifth Avenue, embracing the entire square bounded by One Hundredth, One Hundred and First Streets, Madison and Fifth Avenues, with the exception of three city lots. Voluntary subscriptions are sought to defray the cost of the buildings, about $350,000 having been collected up to this time, we are informed. It is proposed to spend twice this sum for the building, which is to be equipped as a modern scientific hospital in the fullest sense of this term. Ground will shortly be broken, and it is expected that the new hospital will be occupied by 1900.

American Fruits Free from Dangerous Infection.—The Agricultural Department at Washington has recently completed a series of experiments which prove the falsity of the claims made by several European governments upon which American fruits have been excluded from their markets. These governments shut out American fruits on the charge that they were infected with what is called the "San José scale." The experiments of the Department of Agriculture have been most minute and careful. Large lots of peaches, pears, and apples infected with the "scale" have been tested by all known methods of commercial drying, sun drying, by evaporation, by using sulphur and without, with the result that each of these processes destroys the life of the "scale." It has also been demonstrated that the "scale" does not destroy the flavor of the fruit, and is perfectly harmless when taken into the human stomach. The presence of the "scale" may be recognized by a very small, dark spot on the fruit, growing in size as the "scale" multiplies.

SPECIAL ARTICLE.

YELLOW FEVER AT SANTIAGO.[1]

SIR:—Pursuant to your instructions of August 20, 1898, to proceed to Santiago de Cuba, for the purpose of testing the serum in suitable cases, both as a curative and as a prophylactic agent, I did so at my earliest opportunity, arriving in that city on August 25th. Consultation with the military officials of our Government in command convinced me that the rumors prevalent in the United States of the malarial character of the prevailing fever at Santiago rather than yellow fever was correct. The officials of the city declared that there was no yellow fever in Santiago; therefore, I refrained from visiting the city hospitals, because of the consumption of time, and the inadvisability of a difference of opinion as to diagnosis in any possible cases seen there. However, the surgeon-in-chief of the military commandant of the province of Santiago assured me of the presence of the disease, as reported to him by his subordinate officers, and gave me *carte blanche* to enter the hospitals at both Siboney and on the island in the bay set apart for the purpose of a yellow-fever camp. Owing to the rapidly progressing discontinuance of the camp at Siboney, I took up my residence at the island hospital. A careful scrutiny of the number of convalescents there, and an inspection of their clinical histories, especially in regard to the pulse and temperature tracings, convinced me that, while there was, in numerous cases, a condition resembling yellow fever, yet the pulse and thermographs did not fulfil the demands as enunciated by J. C. Faget[1]; that, while the pulse-tracings were generally low there was an absence of the typical "want of coordination" seen in an *ascending* or *stationary* fever at its acme, together with a *falling* pulse. There was much food for reflection, and I was finally convinced that in all of these cases, showing an intermitting type of fever, and most of them an enlarged spleen and tender liver, a malarial intoxication was present. Yet could the slow pulse, spongy gums, yellowish (not pronounced) skin and eyes, skin extravasations, depend upon yellow-fever infection? I had reason to question the statement of "albumen in the urine" in some cases, since I was led to doubt the competency of the analyst. A continued study of these facts and of the cases arriving of so-called yellow fever, led me to the conclusion that the *ensemble* of symptoms which had been so freely thus diagnosed was due to a very general condition of incipient, or developing scorbutus, upon which there had become implanted a malarial toxemia. To me this seemed to develop a condition of serious danger but little inferior to yellow fever itself. At no time did I see a case which warranted the use of the curative serum, since the enlarged spleens and other evidences of malarial infection, even if I had accepted the dictum of those in charge of the hospital, would, under Sanarelli's direction, have gone far to negate the results of its use. Under such circumstances I deemed it my duty to acquaint you with the conditions existing, especially since I had before visiting this hospital and examining the patients, reported to you the favorable opportunities to fulfil your wishes in regard to this serum as it was presented to me by the authorities.

In differing from the opinion of the officials of this hospital, I must express my grateful appreciation of their uniform courtesy to me at all times, and of the interest

[1] Special report from advance sheets of the U. S. M. H. S. report upon the effort to test in suitable cases the "serum anti-amarylic," donated to the United States by Professor Sanarelli of the University of Montevideo, Uruguay, with the request that it be tested at the earliest opportunity in suitable cases of yellow fever.

[1] "Monographe sur le type et la specificité, de la Fiévre Jaune," 1875.

there was manifested in the work committed to my charge.

It is but right to say that every official courtesy was extended by Generals Lawton and Wood, and especially by Colonel Havard, the surgeon-in-chief of the military forces occupying the province of Santiago de Cuba.

Respectfully yours,

EUGENE WASDIN,
Surgeon, U. S. M. H. S.

CORRESPONDENCE.

"UNITED STATES HEALTH REPORTS AND CARRIER, M.D."

To the Editor of the MEDICAL NEWS.

MY DEAR SIR:—Your magnificent and refreshing editorial in the MEDICAL NEWS of November 12th upon the sheet bearing the pretentious title "United States Health Reports" and its contents I have read with pleasure. I believe that the profession in general should be particularly grateful to you for your elaborate dissection of the expressions used by the author of said article, and the concise explanation of its true meaning.

Yours truly,
W. STEVENS, M.D.

70 WEST FIFTY-SECOND STREET,
NEW YORK, November 15, 1898.

THE PROPER USE OF OBSTETRIC FORCEPS.

To the Editor of the MEDICAL NEWS:

DEAR SIR:—I have read with great interest the article published in your journal of October 22nd on "The Use of Obstetric Forceps, with Report of Two Cases of Inversion of the Uterus." Many valuable practical points were given by the writer in the use of forceps, and certainly too much cannot be said or written on this very interesting topic. But there are several thoughts expressed by the author of the paper with which many obstetricians will not agree. A few of these are of so much importance that a little time and space can well be afforded them.

The writer says among other things: "Some authors advise the removal of the forceps before the head is delivered and as soon as you can grasp the chin with the index-finger in the rectum, but I prefer to leave the forceps adjusted until the delivery of the head is completed." In preference to the method of introducing the finger into the rectum (a procedure which, to my mind, is never necessary, and which should be for lack of cleanliness carefully avoided) I also would choose to leave the forceps adjusted until the head is born, but is it not better to remove the blades before the birth of the head? I believe that for several reasons the forceps should be removed at the moment when it becomes evident that the labor can be completed without them. In other words, when the vulva and perineum are well on the stretch, when the head between pains recedes but little, and when the head can be lifted up by the hand, pressing upward upon the forehead through the soft parts, the head can be delivered more carefully and with less likelihood of perineal laceration than when the forceps are left in place. Experience is necessary in order to judge with accuracy the precise moment at which the blades can be removed, but to my mind the operator in gaining the knowledge of technic will get better results by removing the blades a little too early than to keep than in place too long. By delaying the removal, he may, and often does, lacerate the perineum, when such rupture could easily have been avoided. If removed too early it will be an easy matter to replace them and advance the head sufficiently to be able again to remove them.

During the latter part of delivery, especially in cases where the pains, in spite of the chloroform, cause rapid advance, the head can be controlled far better with the hands than with the instrument. The blades, too, take up room at the outlet, and there are cases in which the perineum will stretch sufficiently to allow the head to pass, but which will be torn if put further upon the stretch by the additional thickness of the blades. But the chief objection to leaving the forceps applied is that already stated, namely, that the head can be controlled better and a more careful delivery made when the blades have been removed. In primiparæ, this is particularly true and of great importance. During the removal of the blades the head must be controlled by the hand, or at an unexpected moment advance may be rapid enough to complete delivery, not to our satisfaction because of laceration that might have been avoided. In an experience of several hundred forceps cases I have seen a number in which laceration occurred during the few seconds required for the removal of the blades where, by a careful appreciation of the fact that resistance had been almost entirely overcome and that a moderately strong pain would therefore advance the head rapidly, a laceration would have been avoided.

In the treatment of occipitoposterior positions, I must disagree with the writer, who says, "In cases of occipitoposterior position it is always best to refrain from using forceps as it prevents rotation, yet where speedy delivery is required, it is best to apply forceps to the sides of the head, and to imitate the mechanism of normal labor in posterior positions. If the sagittal suture occupies an oblique diameter, the forceps should be applied in the opposite oblique, as the occiput should be rotated into the hollow of the sacrum." The writer then says that the lines of traction are the same as in the ordinary vertex presentation, only the face rotates under the arch. All will agree, I think, that the use of forceps in cases of posterior position should be avoided until it is evident that Nature can accomplish no more, or until the condition of the mother or child requires it. Oftentimes, several hours are required to complete flexion and cause rotation to occur, and, therefore, it is well to give the natural forces time in which to operate, even if action is slow. But, when advance ceases or where, for some reason the welfare of the mother or child demands it, it becomes necessary to use forceps let us imitate the mechanism of normal labor by causing rotation to the front, not into the hollow of the sacrum. The great majority of cases

of occipitoposterior position terminate by rotation and therefore that course must be taken as the normal. Therefore, rotation should be attempted with the forceps, provided of course the head be low down in the pelvis. This is a condition which must be complied with, for rotation in the middle of the pelvic cavity is often difficult and much more dangerous to the soft parts. If the head is still high up, it should be brought well down to the outlet, where flexion can be increased with the forceps, and where there is more room in which to rotate. Having brought the head well down, so as to distend the perineum well, rotation can, as a rule, be easily accomplished, great care being taken that the head be held firmly, that the tips of the blades are not allowed to lacerate the soft parts, and that the fingers of one hand be placed upon the head (to indicate amount of turning) while rotation is performed by the forceps in the other hand. Straight forceps are excellent for such cases, but the forceps with the pelvic curve are safe, provided the operator keeps in mind the direction in which the tips of the blades are moving, and operates slowly and carefully. Failing to succeed in the rotation, the head should be brought still further down and the effort repeated. Careful attempts to rotate should certainly be made, for there is greater danger of rupture of the perineum, should the head be brought though in the posterior position. If in any case the head cannot be made to rotate, delivery, of course, must be made in the posterior position.

One point which must be emphasized is, that after the head has been rotated, it must be held in the anterior position until the uterus has relaxed sufficiently to allow the body to turn also. The amount of rotation should be not more than 90°, for that is sufficient, as a rule, and there is no danger of twisting the child's neck. Nature will aid very greatly in the rotation, provided a little assistance be given at the outset.

It is safer also to apply the forceps for the purpose of rotation in the same manner as for an anterior position, reapplying the blades after the turning is accomplished.

Only expert operators should, I believe, apply forceps in the "inverted" manner spoken of by some authors. In breech-presentations the forceps should be used only in those cases where the delivery of the after-coming head can be slowly and carefully made, and, therefore, in cases where efforts to deliver the head by the ordinary methods have failed. The child being dead the remainder of delivery can be slowly completed, either with the forceps or cephalotribe.

Manual methods of traction aided by expression are far better than instruments for the delivery of the after-coming head, and delay here for the application of forceps would be a dangerous one.

We agree with the writer perfectly when he states that "in the early use of forceps and with proper precautions, they will be hailed as a welcome boon to the woman in labor."

GEORGE L. BRODHEAD, M.D.

60 WEST FIFTY-EIGHTH STREET,
NEW YORK, November 17, 1898.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

WATER-POLLUTION AND ITS PREVENTION BY STATE CONTROL — A POLICE CRUSADE—THE PENNSYLVANIA INSTITUTION FOR TEACHING THE BLIND—CASTOR-OIL POISONING—MEMORIAL SERVICES TO DR. PEPPER—CASES PRESENTED TO THE PATHOLOGICAL SOCIETY — A PHYSICIAN CENSURED—HEALTH-BOARD STATISTICS.

PHILADELPHIA, November 21, 1898.

WHILE City Councils are dawdling over various schemes for the filtration of our water-supply, and the local community continues to sit with folded hands, doing nothing, saying nothing, the State Board of Health is not only arousing public sentiment but taking active steps to overcome the pollution of the various streams of the State. Dr. Benjamin Lee, secretary of the Board, in his annual report declares that the typhoid fever existing in Philadelphia can be directly traced to the pollution of the Schuylkill, and suggests that a law be passed by the next Legislature giving the State Board of Health direct control over all water-supplies and the appointment of wardens whose duty it shall be to patrol the streams and report violations of the law.

The arrest of a fortune-teller, whose supposed revelations of the future had driven her client insane, has started a crusade against this class of individuals, and many "faith-curists," "magnetic-doctors," and the like will probably find themselves within the meshes of the legal net before the rounding up ends. It seems a pity that the law cannot go further and arrest venders of "female regulators," "No. 7 specific," etc., who advertise most brazenly in the newspapers to secure by means of drugs that, which in law, is considered a criminal operation. Perhaps when the millennium comes Mr. Munyon, who is now filling our drug-store windows with a horde of uniformed employees, using atomizers and other nauseating toilet articles before the public, will also fall into the clutches of the police for obtaining money under false pretences.

The Pennsylvania Institution for Teaching the Blind, at Overbrook, will be formally opened next month. The building, which has been in the course of construction for eighteen months, is three-stories high, with a frontage of 300 feet, and two wings extending about 320 feet. Besides this main building there are detached buildings for the hospital, kindergarten, and the residence of the superintendent.

A case which was puzzling for the reason that the cause of death was not discovered until the coroner's inquest occurred this week in a child aged four years. The child was taken suddenly and violently ill, and died within a short time, the father stating his belief that some beans which the child had taken from an uprooted plant in a vacant lot had poisoned her. Upon investigation it was found that the beans were taken from a castor-oil plant, and that they had caused an acute nephritis from their poisonous and irritating action. Several other children in the same neighborhood were made very ill, but no other casualities beyond the one mentioned have been recorded thus far.

On Tuesday evening, November 29th, a meeting will be held in the chapel of the University of Pennsylvania in memory of the late Dr. William Pepper. The arrangements are in the hands of a joint committee representing the University, the American Philosophical Society, the Franklin Institute, the Academy of Natural Sciences, and other city institutions, and representatives of most of these institutions will deliver short addresses. Governor Hastings, as President *ex-officio* of the Board of Trustees of the University, will preside, while Dr. S. Weir Mitchell, on behalf of the Board of Trustees, will make the first address of the evening. Dr. Tyson will deliver an address as representative of the medical faculty, and among others who will speak are Frederick Fraley, W. P. Wilson, John Thomson, Mayor Warwick, General I. J. Wistar, Daniel Baugh, and Hampton L. Carson.

Dr. J. H. Jopson presented specimens of an epithelioma of the penis and an osteosarcoma to the Pathological Society last week. The epitheliomia was removed from a man aged fifty years, and had encircled the meatus, extending up along the spongy body. The osteosarcoma was removed from the right pectoralis major muscle of a boy, and was secondary to an osteosarcoma of the clavicle, which had been removed sixteen months previously.

Drs. George E. de Schweinitz and J. D. Steele presented several tumors of the eye, one of which, a carcinoma of the choroid, was secondary to an operation performed six months previously for removal of the breast for carcinoma.

Dr. J. M. Swan showed a specimen illustrating an anomalous position of the cecum which was situated in the umbilical region. Dr. Hare spoke of the frequency of similar conditions and the importance of their recognition in diagnosis, while Dr. Coplin said malposition of the intestines was very frequent in the insane.

At an inquest held by Deputy Coroner Dugan this week a physician was severely censured for not reporting a case in which there was a decided suspicion of malpractice. A young woman died of peritonitis after having been attended by a medical student on several occasions, and while it was impossible to fix the guilt upon the latter, the coroner said his convictions were decidedly opposed to those of the jury who acquitted him, and he regretted his inability to hold the student for the Grand jury.

The total number of deaths occurring in Philadelphia for the weeking ending November 19th, as reported at the Health Office, was 414, of which 116 occurred in children under five years of age. The total number of new cases of contagious diseases was 227, reported as follows: Diphtheria, 114 cases with 23 deaths; scarlet fever, 17 cases with 2 deaths; typhoid fever, 96 cases with 9 deaths.

OUR LONDON LETTER.

[From Our Special Correspondent.]

THE GROWING USE OF ANTISEPTICS IN ARTICLES OF DIET—MEETING OF THE BRITISH GYNECOLOGICAL SOCIETY—DISCUSSION ON METHODS OF SUTURING AFTER ABDOMINAL SECTION—THE OPEN-BOWEL TREATMENT—A SCHOOL FOR CLINICAL INSTRUCTION IN TROPICAL DISEASES.

LONDON, November 11, 1898.

A GOOD deal of alarm has been awakened here in both medical and lay circles during the past few weeks over the wide and increasing use of aseptics and antiseptics of various sorts in articles of diet under the title of "Food-Preservatives." For obvious reasons they are particularly common in milk and butter and a few days ago Dr. Winter Blyth, health-officer to the Marylebone Vestry (one of the ancient "parish" divisions of London) reported the discovery among some samples of milk he was testing of a lot containing five grains of boracic acid to the pint.

The use of such antiseptics appears to be much more frequent here than in America as yet, for it is a common thing to see a row of these food-preservatives occupying a prominent place in the drug stores, with full directions for use. Boracic and salicylic acids and solutions of formalin seem the chief favorites. Fortunately, most of these are considered comparatively harmless in the amounts which can be used without affecting the taste of the food, but as articles of diet there are grave objections to them, especially as nothing is known of the effects of their continued use. The most serious objection to the custom, however, is that dairymen relying upon them, will come to disregard proper precautions as to cleanliness of milking, of the storing, and of the vessels, and thus permit the contamination of the milk by ptomains, germs, or toxins against which these "parlor antiseptics" are, practically, of course, absolutely inert.

At the last meeting of the British Gynecological Society after the exhibition of specimens recently removed, the discussion of Christopher Martins' paper "Some Moot Points in the After-treatment of Cases of Abdominal Section," adjourned from the previous meeting, was taken up. As the paper had in the mean time been printed and a copy sent to each member, the discussion had a full-bodied, partisan flavor, in the impromptu "discussion-limited-to-ten-minutes" debate but it also had the disadvantage of being rather long. Each member had brought his copy, with the strategetic points of attack marked in pencil, and the result was that the only other paper of the session was, from lack of time, shelved in its turn for discussion at the next meeting. This method certainly increases the sufferings of the writer, but is probably better for the subject. From the opinions expressed well-nigh every point in the after-treatment appeared to be a "moot" one. Martin had advocated single-line sutures of silkworm-gut, McNaughton Jones, and Jessett preferred the triple set, but disagreed as to the peritoneal row, the former using silk, the latter catgut, both regarding ventral hernia or strain after vomiting as less liable to occur after this method. Bantock advocated the

single suture and thought stitch-abscess chiefly due to too tight stitches or including too much tissue in their grip, which McNaughton Jones protested against, blaming the suture materials. Martin permitted the patient to be turned on her side by the nurse after twenty-four hours. Lawrie and McNaughton Jones kept her absolutely at rest on her back for forty-eight to seventy-two hours. Nearly all agreed in strictly limiting the patient to hot water by teaspoonfuls for twenty-four hours, but no mention was made of our method of filling the peritoneal sac or injecting the large bowel with normal salt solution to allay thirst.

Martin advised the routine use of morphin, giving the first dose before the patient was taken off the table. Lawrie objected because he had once lost a case after ¼-grain dose, and was sustained by Jessett, and the President, Dr. Jones, and Dr. Tanners, who protested against routine use.

In the management of the bowels, Jessett gave an enema upon the second day, which Dr. Tanners regarded as dangerous and preferred like Martin himself a calomel purge on the second day if symptoms demanded it, if not on the fourth day. Other speakers advocated magnesium sulphate in teaspoonful doses frequently repeated.

The new paper of the evening by Stanmore Bishop upon "Combined Abdominal and Vaginal Section in Pelvic Surgery," was a description of four cases of pelvic growths and adhesion in which the vaginal route had to be abandoned and the abdomen opened above. He discussed the general problem of the comparative advantages of the two routes, holding that far too much had been claimed for the vaginal operation, which was attended by serious difficulties and risks in a considerable and increasing minority of cases; was also liable to result in hernia and, although involving less immediate shock than the abdominal, was ultimately attended by even greater risks.

Mr. Chamberlain has just announced on behalf of the Colonial Office that a school for clinical instruction in tropical medicine will be opened for the benefit of Colonial medical officers. The Seamen's Hospital at the Albert Docks will be utilized for the school, and it is intended to collect both cases and material from the various colonies. The English authorities have learned by bitter experience as we also have during the past summer that the white man's deadliest foe in the tropics is disease, and disease often of a peculiar nature, in which Northern experience and training, however thorough, may be almost utterly useless. An important feature of the school will be well-equipped laboratories and a permanent commission for the investigation of tropical diseases, which is both more advisable and hopeful now that we are finding out that these "jungle" and "seasonal" fevers are caused not by the climate but by bacteria.

THE PLAGUE AT VIENNA.

[Special Correspondence of the MEDICAL NEWS.]

VIENNA, November 10, 1898.

VIENNA has had another experience with the bubonic plague. By the time this reaches you the general details will have been presented in your columns but the recital of a few of the more technical medical points involved may prove of interest to your readers.

The class in practical bacteriology at the Pathological Institute, of which I am a member, had as man of all work in the laboratory a certain Barisch. Early on Saturday morning, October 21st, he was taken sick with a chill and general symptoms of influenza. Dr. Ghon, the

DR. HERMANN FRANZ MULLER,
Who recently died of the plague at Vienna.

bacteriologist of the General Hospital, examined his sputum for the purpose of obtaining specimens of the influenza bacilli for demonstration to his class. Instead of finding these, however, he discovered what appeared to be attenuated forms of the pest bacillus. Drs. Ghon, Albrecht, and Müller were sent to India last year by the Austrian government for the purpose of studying the plague, the former as bacteriologist, Albrecht as pathologist, and Müller as clinician. Barisch was under the clinical care of Dr. Müller, and to him Dr. Ghon communicated

ALBINA PECHA,
The nurse who died of the plague while in attendance upon Dr. Müller.

his suspicions that the case was one of plague. The clinical appearances, however, were of pneumonia, and there was none of the signs of lymphatic involvement common to plague, so the bacillary diagnosis was not fully heeded. The pest bacillus is a slow-growing organism, and it was not until the following Wednesday, October 25th, that the cultures showed conclusively that the man, who in the meantime had died, had suffered from a genuine case

of the plague. He had grown worse so rapidly that he had been isolated, though still at the General Hospital.

Not long after the death of Barisch Dr. Müller and one of the nurses in attendance were taken ill with the disease. They were promptly taken to the Epidemic Hospital and there isolated, but both died from the infection. Several other persons who had been exposed and were slightly ill were also isolated for the purpose of observation, but only one proved to have the disease, there being three deaths in all from this cause.

Just how the original infection occurred cannot be definitely determined. Upon their return from India Drs. Ghon and Albrecht continued their studies of the disease by means of experiments on animals, a room at the Pathological Institute being set aside for their use. No one except themselves and Barisch was allowed to enter this room. Early in the present year they did a good deal of work along the special line indicated, having many animals infected with the plague, but at the time at which Barisch was infected their investigations had been nearly completed, only a few animals being in the laboratory, and on these experiments were being made to produce immunity. Barisch had been instructed as to the means of avoiding infection, and had been a very efficient and faithful assistant. Dr. Ghon had wished to immunize him, but this he had declined. Whether he finally became infected through some wholly accidental means or not can only be surmised. To support the latter theory there is the testimony of his wife, who says that while he had usually been a temperate man, of late he had been drinking heavily, remaining out late at night, and frequently coming home under the influence of liquor. This of course gives color to the supposition that while not in complete possession of his faculties he may have been careless in handling some of the infected material at the laboratory, and so become inoculated with the germs of the disease.

Cathedral in Vienna.
A thank offering for the staying of the plague.

Vienna has had more than one sad experience with the plague, and so it is not to be wondered at that the people should take alarm that a death should have occurred from this cause in the city, and should have feared that a general epidemic was to take place. Strange as it may seem, political capital was made out of the occurrence also. Barisch died in Professor Nothnagel's clinic. While Nothnagel is not himself a Jew, he has done much to aid the people of this sect at different times, and in more ways than one has shown his sympathy for them in their unfortunate position here in Austria. The antisemetic element made this the occasion for a violent and wholly unreasonable attack upon him, certain members of the present city government, the mayor, and the official press joining to heap contumely upon him. Fortunately, this has had but little effect in lowering him in the opinion of those who know his devotion to scientific medicine. But the occurrence of the plague here has resulted in a sad blow to the Pathological Institute, as all the animals at the Institute have been killed, and among these were many completely and partially immunized against the plague. The Institute was closed at once and all clinical instruction at the General Hospital was discontinued for two weeks. Things have regained their normal tone now, however, and the clinics and laboratory work are going on as usual.

Dr. Müller was an exceedingly brainy man, and though but thirty-two years of age had made an enviable reputation for himself as a diagnostician and teacher. Public subscriptions are being made for a monument to him, and between six and seven hundred dollars has already been collected for this purpose. I enclose a photograph of Dr. Müller, who contracted the disease while in voluntary attendance upon Barisch and whose death must therefore be regarded as a sacrifice to professional duty, and the photograph of the faithful nurse, whose devotion to duty commands the same recognition. It may be interesting also in this connection to present a cut of the cathedral, erected at Vienna as a thank offering for the staying of the plague early in this century.

TRANSACTIONS OF FOREIGN SOCIETIES.

British.

FIBRINOUS RHINITIS AND THE KLEBS-LOEFFLER BACILLUS—TREATMENT OF PERSONS WHO HAVE RECEIVED SEVERE BLOWS IN THE ABDOMEN WITHOUT SIGN OF EXTERNAL INJURY—ADVANTAGES OF VENESECTION IN PNEUMONIA—LUPUS OF THE CHEEK CURED BY X-RAYS.

At a meeting of the Royal Medical and Chirurgical Society, October 25th, Lack read a paper on "Fibrinous and Membranous Rhinitis and Its Relation to Diphtheria." This disease was described by Schuller, in 1871, as a subacute or chronic affection of the nose. It was formerly thought to be distinct from diphtheria, but more recent observers, relying on the results of bacteriologic examination, have claimed that the trouble is simply a mild form of diphtheria. An analysis of thirty-six cases showed the disease to be essentially one of children and

to occur especially in the autumn months. The chief symptoms are nasal obstruction and discharge, with excoriation of the upper lip, attended, sometimes, by sore throat. The affection lasts on the average from six to eight weeks and almost invariably terminates in recovery. Doubtless many cases, on account of the mildness of the symptoms, are never seen at all. Bacteriologic examination was carried out in thirty-three cases and the Klebs-Löffler bacillus was present in every case, sometimes alone, and sometimes mixed with pyogenic cocci, sarcinæ, etc. Its identity was proven by cultures as well as by tests upon animals. Examinations of the surroundings of patients showed that the disease is very contagious and that the bacilli may be found in the throats of healthy people who have been in association with those children. In only one instance could a previous history of diphtheria be found. The conclusion was arrived at that fibrinous rhinitis is a mild variety of diphtheria, the difference in the clinical manifestations apparently depending upon some differences in the Klebs-Löffler bacillus.

MACFADYEN said there were probably several factors in infection: (1) The properties of the bacillus, since the bacilli vary greatly in virulence; (2) the condition of the tissues; (3) the presence and virulence of associated pyogenic organisms, which, by lowering the vitality of the tissues, facilitate the entrance of the diphtheria bacilli.

LISTER had examined the nasal mucus of 125 children. The Klebs-Löffler bacillus was found in thirty-nine of them, ten of whom were free from any nasal discharge whatever. Some of the children were sent home and some were isolated in the hospital, but in no instance did ordinary diphtheria arise from these cases.

GOODALL spoke of the frequency of occurrence of the Klebs-Löffler bacillus in the sore throat of scarlet fever. He had regularly found it in a form of nasal discharge of an obstinate character which sometimes follows scarlet fever. He also called attention to the fact that when a case of true diphtheria gets into a scarlet-fever ward it often follows that none of the scarlet-fever patients contract diphtheria.

At the Medical Society of London, October 24th, SHEILD read a paper on "Four Cases of Abdominal Section for External Injury Not Accompanied by Wound." A boy aged eleven years was run over by a cab and suffered from severe collapse which did not pass off. The abdomen was opened and found to be full of blood from a rent in the mesentery. Another boy was run over by a heavy vehicle and was also in a state of collapse. His abdomen was found filled with blood and the jejunum was torn quite across. End-to-end anastomosis was done, but the patient died of peritonitis. At autopsy an undiscovered tear was found in the duodenum. In a third boy, aged sixteen, the source of the hemorrhage was found to be a rupture in the liver. Iodoform gauze stopped the bleeding easily. A woman, aged sixty, was run over and besides the resulting collapse there was bloody urine. The bladder, however, held boracic solution, and the conclusion was drawn that there was no perforation of that viscus. As the patient grew worse the abdomen was opened and the bladder was found to be badly bruised but not torn through. No other lesion could be found. Pyemic symptoms slowly developed and after death there was found an abscess in the neighborhood of the right kidney, starting from a rent in the posterior wall of the cecum.

In discussing the indications for operation in these cases SHEILD said that the diagnosis of rupture of the kidneys and bladder could usually be definitely made, but that it was often with the greatest difficulty that one could tell whether or not there was serious injury of the intestine, mesentery, spleen, liver, or sympathetic nerves. As a general rule after severe injuries of the abdomen with progressing unfavorable symptoms, exploration is indicated. The mortality of such operations is due to the gravity of the accident and most of the deaths are simply failures to save lives otherwise certainly doomed. It is of the greatest importance that such experiences should be related.

FOWLER mentioned a case in which obliteration of liver dulness had led him to expect a fatal issue in a case which he had diagnosed as perforation of a chronic ulcer. The patient recovered, however, the normal percussion-note of the liver gradually returning.

TURNER mentioned several instances of severe blows upon the abdomen without sign of external injury. He held strongly the view that in grave injury surgical exploration should be resorted to, but he reminded his hearers that in the old days such accidents were not always fatal, even without surgical intervention, as shown by the specimens in many museums of injuries of this character which had healed spontaneously.

BATTLE insisted on the importance of watching cases of abdominal contusion from hour to hour, as serious symptoms sometimes develop suddenly. He had seen one such case in which the patient, a man, after being run over, suffered no pain and was free from anxiety for four days. He then developed fever and in a few hours he was dead. Autopsy showed that there had been a contusion of the small intestine which had caused necrosis and finally perforation of the intestinal wall. The amount of shock affords little evidence as to the severity of the intestinal lesion. Indeed there are no absolutely reliable symptoms for these cases.

SHEILD said that he did not place much reliance upon percussion in abdominal contusion. The tenderness usually precludes careful percussion and even when fluid is present its presence is apt to be masked by distended intestinal coils. The disappearance of hepatic dulness might be due to intestinal distention as well as to free gas in the peritoneal cavity.

BENHAM read a paper on "The Advantages of Venesection in Cases of Acute Pneumonia," the study being based upon nineteen applications of this method of treatment. All of the cases were severe and in several of them life had undoubtedly been saved by the blood-letting. Although venesection affords relief in most cases of acute pneumonia and when performed in moderation never does the least harm, yet, as slight cases recover without this measure it is indispensable only in grave cases. The aim of the reader was to convert a severe

case into a mild one by subduing the overintensity of the morbid processes. Pneumonia is a disease the symptoms of which increase in intensity from day to day till the crisis is reached, and it is possible to check this intensity if it is progressing too rapidly, by blood-letting. A rapidly increasing frequency of the pulse and mental disturbance shown by sleeplessness and wandering are the best indications that venesection is imperatively demanded.

FOWLER said that it is half a century since antiphlogistic theories have been laid aside and that while it is possible that the pendulum has swung too far in the other direction, and while he was willing to admit that venesection could be of service in distention of the right side of the heart, as occurs in chronic bronchitis with emphysema, he was not ready to admit that it was a desirable treatment in pneumonia.

At a meeting of the Liverpool Medical Institution, held October 20th, HOLLAND exhibited a boy, aged ten years, who had suffered from "Lupus of the Right Cheek," which he had treated by the X-ray, eighteen exposures, with the result that the ulcer had entirely healed. The scar was supple three months later and there was no sign of a recurrence. For five years previously the lad had been treated by scarification and cauterization and in many other ways without apparent benefit. He thought the risk of dermatitis from the X-rays has been much exaggerated. He had used it 700 times and had never observed any ill effects from it.

TAYLOR had treated with X-rays two cases of lupus of the face without good result. In a third patient whose lupus was complicated by a corneal ulcer, an inflammation of the eye had been caused by the exposures to the X-rays.

REVIEWS.

THE MEDICAL NEWS VISITING-LIST FOR 1899. Weekly (dated for 30 patients). Monthly (undated for 120 patients per month). Perpetual (undated for 30 patients weekly per year). Perpetual (undated for 60 patients weekly per year. Philadelphia and New York: Lea Brothers & Co., 1898.

THIS well-known Visiting-List barely needs description at our hands. It is issued this year in the same handsome wallet-shaped form as heretofore. The work gives printed data of a valuable and useful kind, such as a table of remedies alphabetically arranged, a table of doses, notes for examination of the urine, poisons and their antidotes, incompatibles, artificial respiration, a diagnostic table of the eruptive fevers, and a full-page plate showing the incisions for the ligation of the various arteries. This Visiting-List embraces features peculiar to itself of decided value, and is issued in styles intended to meet the wants of all practitioners.

A MANUAL OF OTOLOGY. By GORHAM BACON, A. M., M.D., Professor of Otology in Cornell University Medical College, New York. With an Introductory Chapter by CLARENCE J. BLAKE, M.D., Professor of Otology in the Harvard Medical School, Boston. Philadelphia and New York: Lea Brothers & Co., 1898.

WHILE not replacing any of the standard references Dr. Bacon's little book condenses into a convenient guide the essential facts of modern otology. The style is terse and readable and leaves nothing for the student to imagine. Diagnosis and treatment especially are made clear without the omission of important details.

The chapter on mastoid diseases, however, is somewhat disappointing in its brevity and the description of the surgery of mastoid complications is incommensurate with the importance of the subject. The work is freely illustrated.

PATHOLOGY AND MORBID ANATOMY. By T. HENRY GREEN, M.D., Lecturer on Pathology and Morbid Anatomy at Charing-Cross Hospital Medical School, London. New (8th) American, from the eighth and revised English, edition. Philadelphia and New York: Lea Brothers & Co., 1898.

THAT this work should have passed through eight English, and as many American editions, is ample testimony of its continued recognition as a standard text-book. Dr. Walton Martin, who revised this last edition, has effected a noticeable improvement in the arrangement of the subject material. By adopting a different system of classification he has made the text more convenient for reference, and more logical for order of reading. While the work is free from lengthy discussions and from descriptions of experiments due note is made of recently derived data in pathology and of the most modern theories in cytology and bacteriology. The book is handsomely illustrated.

A TEXT-BOOK UPON THE PATHOGENIC BACTERIA. For Students of Medicine and Physicians. By JOSEPH MCFARLAND, M.D., Professor of Pathology in the Medico-Chirurgical College, Philadelphia; Pathologist to the Medico-Chirurgical Hospital and to the Rush Hospital for Consumption and Allied Diseases, Philadelphia. Second Edition, Revised and enlarged. Philadelphia: W. B. Saunders, 1898.

THIS is an admirable book in many respects, and physicians in particular will find much of interest in it. As a text-book for students, however, there is much that could have been omitted. In the preface we are informed that "the work being upon pathogenic bacteria, it does not cover the whole scope of parasitology, and the parasites of higher orders are all omitted. Malaria and amebic dysentery are omitted as logically as tapeworms and pediculi." Still we find several pages describing in detail the disinfection of the hands in surgical procedures and the preparation of ligatures, the disinfection of sick-rooms, the disposal of dejections and sputum, and the care of patients during convalescence from infectious diseases, all of which may be found in any modern work on medicine or surgery and does not logically find a place in the work before us.

The book contains a vast amount of information on the subject of bacteriology and the matter is presented in a

clear and pleasant style. All of the most recent discoveries and works in the field find mention in the present edition, the references to the original sources being of great value. The author describes at length the serum reaction in typhoid fever, giving preference to fresh agar-agar cultures distributed in sterile water to bouillon cultures, and also recommends the use of capillary tubes for the accurate dilution of the blood.

There are so many practical suggestions throughout the book that it cannot but prove of great value to all workers in bacteriology and to those interested we cordially commend it as thoroughly reliable and accurate. The paper, illustrations, and book-making are of the highest order and leave nothing to be desired.

THE ESSENTIALS OF HISTOLOGY, DESCRIPTIVE AND PRACTICAL. For the Use of Students. By E. A. SCHAFER, LL.D., F.R.S., Jodrell Professor of Physiology in University College, London; Editor of the Histological Portion of Quain's "Anatomy." New (fifth) Edition, Revised and enlarged. Philadelphia and New York: Lea Brothers & Co., 1898.

AN extended review of this book, so well known to students, would indeed seem superfluous. In the present edition much has been added, particularly in the chapter on the nervous system, and the whole work has been brought so well up to date that as a text-book for the student it leaves nothing to be desired. The general plan and arrangement are identical with previous editions, the beautifully executed illustrations being especially valuable and instructive.

We have only one suggestion to offer: that in the appendix a more detailed explanation in the technic of preparing histologic specimens would greatly enhance the value of the book. With this exception the work stands at the head of its kind and no student will regret having it in his possession.

THE OHIO STATE MEDICAL SOCIETY. Transactions of the Fifty-third Annual Meeting, held at Columbus, Ohio, May, 1898. Cleveland, Ohio: J. B. Savage Press, 1898.

A HANDSOME portrait of the president, Dr. William H. Humiston, is the frontispiece of this volume. The editor, Dr. P. Max Foshay, has given us a rather unique book, in that the papers read at the meeting are grouped under the respective heads to which they belong. The articles are up to the usual high standard of this society and the volume will be a pleasant memento of what must have been an interesting meeting.

YELLOW FEVER—CLINICAL NOTES. By JUST TONATRE, M.D. (Paris). Translated from the French by CHARLES CHASSAIGNAC, M.D. New Orleans: New Orleans Medical and Surgical Journal, 1898.

THIS book is the result of the author's experience gained in the treatment of more than two thousand yellow-fever patients. It considers the subject chiefly from a clinical standpoint. As such it is very valuable, because the descriptions of this disease in the various text-books are not often based on personal experience. The author calls special attention to Faget's law of divergence between pulse and temperature, and to the same physician's observation of the fall of pulse-rate in this disease. He regards these two symptoms as pathognomonic of yellow fever, yet he says they are very little known, imperfectly observed, and badly appreciated.

Dr. Tonatre considers that the question of temperature in yellow fever regulates everything,—the diagnosis, the prognosis, and the treatment. He is not at all modest in reference to his own skill and knowledge of the disease, and does not hesitate to affirm them whenever he can.

RECORDS OF URINARY EXAMINATIONS. A Convenient Method for Keeping Records of Urinary Examinations for Future Reference in Hospital or General Practice. Arranged by HARRY MORELL, M.D. Hartford: J. B. Burr & Company, 1898.

THIS volume consists of a large number of alternate white and yellow blanks for urinary reports, arranged so that by means of carbon paper, two records can be simultaneously made. The white sheets are detachable, so that a copy of the results of an examination can be given to the sender of the specimen. On each page is a list of the ingredients to be tested for, with space at the side for the filling in of the results. Hippuric acid, creatinin, xanthin bases, and coloring matters need scarcely to have been taken in account, as they are not usually tested for in clinical examinations. Diacetic acid might have been added. Space is provided for an index. The book is bound in oiled cloth so as to be easily cleansed after use in the laboratory.

THERAPEUTIC HINTS.

For the Constipation Accompanying Ovaritis.—

Spts. menthæ pip. . . . . q.s.

M. Sig. One teaspoonful in a glass of water at bedtime.—*Winternitz.*

For Pertussis.—

℞ Tinct. digitalis . . . . . *m.* xv
Antipyrin . . . . . gr. xxx
Tinct. opii camphoratæ . . . ʒ i
Syr. tolutani . . . . . ʒ ii.

M. Sig. One-half teaspoonful three times a day.—*Koplik.*

For the Dysphagia of Tubercular Laryngitis.—KASSEL claims for this symptom an efficient remedy in an emulsion of one part orthoform in four parts olive oil to be injected directly into the larynx by means of a suitable syringe. Orthoform when thus applied does not provoke the violent fit of coughing which follows insufflation of the drug, and its full analgesic action is therefore gained. After a momentary burning sensation there comes a feeling as of a foreign body in the larynx which marks the beginning of an analgesia lasting often for twenty-four hours. No effect on the lesion is obtained but the secretion of the ulcerated parts is noticeably diminished.

ORIGINAL ARTICLES.

RESUME OF ONE HUNDRED CASES OF TUBERCULOSIS.

BY HERBERT MAXON KING, M.D.,
OF GRAND RAPIDS, MICH.

THE one hundred cases of tuberculosis from which I gather the following statistics have come under my observation within the past four years, and include all those in which I have kept tabulated histories and notes with a special view to studying the etiology, primary lesion, subsequent distribution of foci, intercurrent complications, prognosis, and causes of death. The immense field thus suggested cannot be discussed within the narrow limits of a brief paper, and I shall confine myself, therefore, to these subjects as they affect these one hundred patients only. The advantage to be gained from considering cases to be reported in groups of one hundred is simply that all figures represent percentages, which for purposes of generalization is obviously a convenience. At the same time, I am fully aware that generalizing from a report of one hundred cases must be done with cautious conservatism, as the number in itself is too small to warrant conclusions in a broad sense.

In studying the etiology I have endeavored (*a*) to ascertain the influence, if any, of heredity, and (*b*) to establish, if possible, a clear history of infection. In the first instance I have been forced to the conclusion that the hereditary element in its strict sense, as a causative factor in tuberculosis, is practically insignificant, and while, no doubt, heredity will continue to pose, in the popular mind at least, as a figure of grave importance for a long time to come, it can in the scientific consideration of the causes of tuberculosis be almost entirely left out of consideration.

In a concise yet exhaustive paper on "Heredity in Phthisis," by J. Edward Squire of the North London Hospital for Consumption and Diseases of the Chest,[1] the author, after most thorough and painstaking inquiries, embracing 1000 families, reaches the following most important result: Percentage of the offspring of *phthisical* parents subsequently becoming tubercular, 33.16; percentage of the offspring of *non-phthisical* parents subsequently becoming tubercular, 23.65; percentage of influence due to parents or percentage heredity, 9.51. He then clearly shows that this small "percentage heredity" can be more than accounted for by the greater risk of exposure to which children of phthisical parents are necessarily subjected. Without giving more space to the valuable statistical information contained in this paper by Dr. Squire, I would suggest its perusal by those who do not agree with me on this point of hereditary influences in tuberculosis.

Looking into the heredity of my one hundred cases I have obtained the following results: The father was tubercular in 11 cases; the mother was tubercular in 19 cases; both parents were tubercular in 2 cases; paternal grandfather in 2 cases; paternal grandmother in 3 cases; maternal grandfather in 1 case; maternal grandmother in 5 cases. In a considerable number nothing was definitely known regarding the grandparents, a fact which, of course, makes the figures given under that head of little value. Leaving out of consideration, therefore, the grandparents, there are twenty-eight cases in which one or both of the parents were tubercular.

In one hundred *non*-tubercular persons investigated, and whose heredity I recorded, I found twenty-six whose parents, one or both, died of tuberculosis. I would not from this alone conclude that twenty-six per cent. of all individuals have tubercular parents, yet I do not believe that this figure would be far from correct in expressing the facts if they were known.

Unprejudiced and thorough investigation which it is quite unnecessary to detail here, has convinced me that tuberculosis is more prevalent among the children of tubercular parents than among those of non-tubercular *only* in so far as is to be fully explained by the additional risk of infection obtaining in the case of the former. In evidence that this risk is considerable, Squire found that while six per cent. more of the *male* offspring of phthisical parents than the male offspring of *non*-phthisical parents developed tuberculosis, in the incidence of the *female* offspring, fourteen per cent. more became tubercular among the daughters of the phthisical than among those of the non-phthisical parents; a difference of eight per cent. in favor of female children, who for obvious reasons are more closely associated with the diseased. Now, if the slight increase in favor of the offspring of tubercular parents were to be accounted for by hereditary influence alone it would affect the

[1] *The American Journal of the Medical Sciences.*

male equally with the female children. I clearly appreciate the additional risks of infection to which children of phthisical parents are subjected, and will agree that the disease may originally be so incepted and remain for years latent in the body, finally at one of the "change epochs" in the life of the individual or following some acute disease to take on progressive activity, often when no other theory than that of heredity seems logically to explain its etiology. But this is not heredity at all, and is nothing more nor less than infection, withal that it is difficult to trace its origin to one's perfect satisfaction. Indeed, I am much inclined to believe that phthisical parents impart to their progeny a certain immunity to the disease, a view which is borne out by observation, of which the following incident is an example: A clergyman and his wife, the latter having borne two children after developing pulmonary tuberculosis, took into their household by adoption the orphan child of a non-tubercular family. After surviving the birth of her last child six years the wife died. Both of her children are living and in excellent health to-day, the younger having passed her twentieth year. The adopted child came under my observation at the age of seventeen years, having developed acute pulmonary tuberculosis, from which she died. Satisfactory conclusions upon this point, however, I am aware, can only be drawn from statistics extending over considerable time and embracing thousands of cases.

In the second instance, *i. e.*, that of establishing a clear history of infection, I have not been so fortunate, although I am inclined to think that a more persistent inquiry, such as I have of late practised, would have been rewarded by more satisfactory results. I have been able to find a clear history of infection in twenty-eight of my cases, while in seventy-two the etiology is more or less obscure, obscure at least in so far as I am unable to demonstrate the source of the infection.

Regarding the matter of age, I believe I have met with no new features: Two occurred under the age of 10 years; 19 occurred between the ages of 10 and 20 years; 38 occurred between the ages of 20 and 30 years; 30 occurred between the ages of 30 and 40 years; 7 occurred between the ages of 40 and 50 years; 1 occurred between the ages of 50 and 60 years; 3 occurred between the ages of 60 and 70 years. The youngest case occurred in a female child of 5 years; the oldest in a male of 67 years. Hippocrates states that pulmonary consumption occurs most frequently between the ages of 18 and 35 years, which I think all recent statistics will bear out, as do mine, except, perhaps, as pertain to the first year of life.

Tuberculosis of the glands, bones, and serous membranes occurs frequently among very young children, as is shown by the researches of Froebelius, Bolz, and others, but I have seen relatively few cases of tuberculosis in the very young.

The immediate and exciting causes of the development of the disease in the majority of my patients where no distinct infection could be traced I have found to be in the order of their frequency, grippe, pneumonia, typhoid fever, pregnancy, or lactation, measles, and subacute and chronic gastro-intestinal disturbances. In many instances the disease has been insidious in its encroachment, with no history of any acute manifestation in its onset. As regards sex, forty-three occurred in males and fifty-seven in females.

The primary lesion in tuberculosis is at times and for obvious reasons a matter of considerable difficulty to determine, and my statistics in this respect are, therefore, necessarily only approximately correct, notwithstanding that all care was exercised at the time of first examination, and whenever autopsy was made at the post-mortem with this point in view. I found that the initial lesion occurred in the upper lobe of the right lung in 47 cases; the upper lobe of the left lung in 36; simultaneously in both apices in 8; the cervical glands in 3; the bronchial glands in 2; the bones of the vertebræ in 1; the mesenteric glands in 1; the right kidney in 1, and in the lower lobe of the right lung in 1. It may be of interest to note here that while thirty-three of my cases have been complicated with laryngeal tuberculosis, I have never been able to satisfy my own mind much less to demonstrate satisfactorily that the disease in the larynx was ever the primary lesion either in these thirty-three cases or any others which have ever come under my observation, and I confess that my experience in this respect has made me very sceptical as to the occurrence of primary laryngeal tuberculosis to any appreciable extent.
